This book contains information obtained from authentic and highly regarded sources. While all reasonable efforts have been made to publish reliable data and information, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. The publishers wish to make clear that any views or opinions expressed in this book by individual editors, authors or contributors are personal to them and do not necessarily reflect the views/opinions of the publishers. The information or guidance contained in this book is intended for use by medical, scientific or health-care professionals and is provided strictly as a supplement to the medical or other professional's own judgement, their knowledge of the patient's medical history, relevant manufacturer's instructions and the appropriate best practice guidelines. Because of the rapid advances in medical science, any information or advice on dosages, procedures or diagnoses should be independently verified. The reader is strongly urged to consult the relevant national drug formulary and the drug companies' and device or material manufacturers' printed instructions, and their websites, before administering or utilizing any of the drugs, devices or materials mentioned in this book. This book does not indicate whether a particular treatment is appropriate or suitable for a particular individual. Ultimately it is the sole responsibility of the medical professional to make his or her own professional judgements, so as to advise and treat patients appropriately. The authors and publishers have also attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Except as permitted under U.S. Copyright Law, no part of this book may be reprinted, reproduced, transmitted, or utilized in any form by any electronic, mechanical, or other means, now known or hereafter invented, including photocopying, microfilming, and recording, or in any information storage or retrieval system, without written permission from the publishers.

SECTION 1: Evaluation of the Pediatric Urologic Patient 1

1. History and Physical Examination of the Child 3
Anton Wintner and T. Ernesto Figueroa
2. Laboratory Assessment of the Pediatric Urologic Patient 28
Paul F. Austin and Elizabeth B. Roth
3. Fetal Urology and Prenatal Diagnosis 35
Joao Luiz Pippi Salle and Rodrigo L. P. Romao
4. In-Office Ultrasonography 54
Dennis B. Liu and Max Maizels
5. Pediatric Renal Nuclear Medicine 70
Reza Vali and Martin Charron
6. Prenatal and Postnatal Urologic Emergencies 100
Fernando Ferrer and Patrick H. McKenna
7. Urinary Tract Infections in Children 148
Dana C. Rice, H. Gil Rushton, and Hans G. Pohl
8. Fungal, Parasitic, and Other Inflammatory Diseases of the Genitourinary Tract 212
Aviva Weinberg and William A. Kennedy II
9. Anesthesia and Pain Management for the Pediatric Urology Patient 234
Abraham Rosenbaum, Debra E. Morrison, Shalini Shah, and Zeev N. Kain
10. Office Pediatric Urology 248
Patrick C. Cartwright, Siam Oottamasathien, and Brent W. Snow
11. Principles of Minimally Invasive Surgery 261
Walid A. Farhat and Pasquale Casale
12. Pediatric Fluid Management 271
William Waldrop and Jake Christensen
13. Problems with Transitional Care 279
Dan Wood
14. Embryology of the Genitourinary Tract 285
Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

SECTION 2: The Adrenal 289

15. Adrenal or Suprarenal Gland Development 291
Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan
16. Radiological Assessment of the Adrenal 295
Kourosh Afshar, Douglas H. Jamieson, and Andrew E. MacNeily
17. Adrenal Tumors and Functional Consequences 303
Melanie I. Morris, Julie Franc-Guimond, and Anne-Marie Houle
18. Surgery of the Adrenal in Pediatric Patients 312
Jennifer E. Reifsnyder and Dix P. Poppas

SECTION 3: The Kidney 323

19. Basic Science of the Kidney 325
Heidi A. Stephany, John C. Thomas, and John C. Pope IV

20. Renal Vasculature and Kidney 337
Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

21. Renal Anomalies 348
Gino J. Vricella, Douglas E. Coplen, Paul F. Austin, and Elizabeth B. Roth

22. Fetal and Neonatal Renal Function 367
Rakesh Rao and Akshaya J. Vachharajani

23. Cystic Kidney Disease 381
Roshan P. George and Larry A. Greenbaum

24. Acute Kidney Injury 411
Lawrence Copelovitch

25. Renal Transplantation 419
Alexander C. Small and Shumyle Alam

26. Renal Calculus Disease 431
Pramod P. Reddy and Eugene Minevich

27. Endourology for Stone Disease 442
Janelle A. Fox and Michael C. Ost

28. Renal Parenchymal Imaging in Children 470
Daniel B. Herz

29. Assessment of Renal Obstructive Disorders: Ultrasound, Nuclear Medicine, and Magnetic Resonance Imaging 495
James M. Elmore, Wolfgang H. Cerwinka, and Andrew J. Kirsch

30. Ureteropelvic Junction Obstruction and Multicystic Dysplastic Kidney: Surgical Management 505
Michael C. Carr and Aseem R. Shukla

31. Laparoscopic and Robotic Nephrectomy and Pyeloplasty 515
Daniel Avery and Thomas Lendvay

32. Wilms' Tumor 525
Kristen Scarpato, Patrick H. McKenna, and Fernando Ferrer

33. Surgical Approaches for Pediatric and Adolescent Renal Tumors 548
Victor H. Figueroa and Armando J. Lorenzo

34. Upper Urinary Tract Trauma 562
Ardavan Akhavan and Paul A. Merguerian

SECTION 4: The Ureter 573

35. The Ureter 575
Martin Kaefer

36. Ureteral Development 585
Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

37. The Imaging of Vesicoureteral Reflux and Ureteral Disease 588
David A. Diamond, Jeanne S. Chow, and Frederick D. Grant

38. Ureteral Anomalies and Their Surgical Management 604
Kathleen Kieran and Christopher S. Cooper

39. Megaureter 610
David B. Joseph

40. Ureteral Duplication Anomalies: Ectopic Ureters and Ureteroceles 625
Michael A. Keating

41. Laparoscopic Management of Duplication Anomalies 678
Aaron D. Martin and Craig A. Peters

42. Vesicoureteral Reflux: Etiology—Anatomical and Functional 685
Nina F. Casanova and John M. Park

43. Nonsurgical Management of Vesicoureteral Reflux 693
Jack S. Elder and Mireya Diaz

44. Surgery for Vesicoureteral Reflux 708
John W. Brock III and Douglass B. Clayton

45. Minimally Invasive Approaches to Correct Primary Vesicoureteral Reflux 721
Molly E. Fuchs, Ahmad Z. Mohammed, Daniel G. Dajusta, and Venkata R. Jayanthi

46. Injection Therapy for Vesicoureteral Reflux 729
Anthony A. Caldamone

SECTION 5: The Bladder and Prostate 749

47. Basic Science of Prostatic Development 751
Ellen Shapiro and Hongying Huang

48. Basic Science of the Urinary Bladder 761
Darius J. Bägli and Karen J. Aitken

49. Embryology of the Anterior Abdominal Wall, Bladder, and Proximal Urethra 774
Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

50. Radiologic Assessment of Bladder Disorders 780
Douglas E. Coplen

51. Urodynamics of the Lower Urinary Tract 788
William E. Kaplan and Edward Gong

52. Neurological Control of Storage and Voiding 803
Julian Wan and Kate H. Kraft

53. Neurogenic Voiding Dysfunction and Functional Voiding Disorders: Evaluation and Nonsurgical Management 820
Emilie K. Johnson and Stuart B. Bauer

54. Diurnal and Nocturnal Enuresis 853
Mark Horowitz

55. Constipation and Lower Urinary Tract Symptoms 873
Nicol Corbin Bush, Anjana Shah, Karen Pritzker, Janelle Traylor, and Shabina Walji-Virani

56. Operations for the Weak Bladder Outlet 884
Anthony J. Casale

57. Bladder Augmentation: Current and Future Techniques 911
Bradley P. Kropp, Dominic Frimberger, and Earl Y. Cheng

58. Urinary Diversion 949
Peter D. Metcalfe and Richard C. Rink

59. The Malone Antegrade Continence Enema (MACE) 980
Joseph M. Gleason, P. S. J. Malone, and Martin A. Koyle

60. Minimally Invasive Approaches to Lower Urinary Tract Reconstruction 990
Glenn Cannon, Steven G. Docimo, and Christina Kim

61. Genitourinary Rhabdomyosarcoma and Other Bladder Tumors 1000
Paul A. Merguerian, Lisa Cartwright, and Antoine E. Khoury

62. Exstrophy and Epispadias 1029
Linda A. Baker and Richard W. Grady

63. Unusual Conditions of the Bladder, Including Bladder Trauma, Urachal Anomalies, and Bladder Diverticula 1076
Pablo Gomez III and Marc Cendron

64. Posterior Urethral Valves 1087
Stephen A. Zderic and Douglas A. Canning

65. Prune Belly Syndrome 1108
Andrew W. Stamm, Steven J. Skoog, and R. Guy Hudson

66. Surgical Excision of Urachal Anomalies 1135
Heidi A. Stephany, Jathin Bandari, and Steven G. Docimo

SECTION 6: Urethra, External Genitalia, and Retroperitoneum 1139

67. Basic Science of the Genitalia 1141
Laurence S. Baskin

68. Basic Science of the Testis 1150
Julia Spencer Barthold

69. Gonads, Genital Ducts, and Genitalia 1166
Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

70. Disorders of Sex Development 1173
Joao Luiz Pippi Salle and Rodrigo L. P. Romao

71. Anorectal Malformations and Cloaca 1195
Andrea Bischoff, William R. DeFoor, Curtis A. Sheldon, and Alberto Peña

72. Surgery for Intersex Disorders and Urogenital Sinus 1215
Mark C. Adams, Romano T. DeMarco, and John C. Thomas

73. Hypospadias 1232
Warren T. Snodgrass and Nicol Corbin Bush

74. Pediatric Urethral Trauma and Stricture 1259
Nadya M. Cinman, Jack W. McAninch, and Benjamin N. Breyer

75. Abnormalities of the Penis and Scrotum 1268
Gregory P. McLennan, Kevin M. Feber, and Evan J. Kass

76. Penile Replacement Surgery 1297
Piet Hoebeke and Stan Monstrey

77. Hernia, Hydrocele, Testicular Torsion, and Varicocele 1313
Hiep T. Nguyen and Guilherme Rossini

78. Minimally Invasive Management of Inguinal Hernias 1334
Nicholas G. Cost and Paul H. Noh

79. Cryptorchidism 1345
Thomas F. Kolon and Gregory E. Tasian

80. Surgical Treatment 1359
Daniel P. Casella, Steven G. Docimo, and Francis X. Schneck

81. Testicular and Paratesticular Tumors in Children 1370
Lynn L. Woo and Jonathan H. Ross

82. Tumors of the Retroperitoneum 1381
Gordon A. McLorie and Guy Hidas

SECTION 7: Looking to the Future 1401

83. Tissue Engineering for Pediatric Urology 1403
Steve J. Hodges and Anthony Atala

84. Study Designs and Hierarchy of Evidence 1414
Luis H. P. Braga, Melissa McGrath, and Armando J. Lorenzo

Study Guide Questions 1423

Videos

Videos pertaining to this book can be accessed online at www.crcpress.com/cw/Docimo. The content of these videos can be broken into two categories: those cited and captioned in the text of the book itself, and those comprising a separate Atlas created by Pippi La Salle.

VIDEOS FROM THE TEXT	
No.	**Title**
Chapter 1: History and Physical Examination of the Child	
1.1	Penile measurement.
Chapter 4: In-Office Ultrasonography	
4.1	Infant pop pyeloplasty.
4.2	Strategy to deconstruct normal ultrasound images.
4.3	Strategy to deconstruct duplication.
Chapter 11: Principles of Minimally Invasive Surgery	
11.1a	Describes abrupt changes in physiological parameters prior to CO_2 insufflation.
11.1b	Describes abrupt changes in physiological parameters after CO_2 insufflation.
11.2	Simple access through the umbilical ligament and fascial purse-string suture application.
11.3a	Depicts access for two single-port devices that are available commercially: GelPOINT from Applied Medical.
11.3b	Depicts access for two single-port devices that are available commercially: SILS port from Covidien.
11.4a	Animation depicting the different anatomical details and trocar positions.
11.4b	Retroperitoneal access–note the anteriority of Gerota's fascia and posteriority of the psoas muscle.
Chapter 27: Endourology for Stone Disease	
27.1	Mini-Perc technique.
Chapter 31: Laparoscopic and Robotic Nephrectomy and Pyeloplasty	
31.1	Port placement for child renal surgery. Demonstration of port positions access, securing ports, intra-abdominal views, and orientation to target pathology.
31.2	Right robotic pyeloplasty with conventional laparoscopic exposure.
31.3	Left robotic pyeloplasty.
Chapter 39: Megaureter	
39.1	Megaureter MRU.
Chapter 45: Minimally Invasive Approaches to Correct Primary Vesicoureteral Reflux	
45.1	Laparoscopic Extravesical Ureteral Reimplant.
45.2	Laparoscopic Vesicoscopic Reimplant.
45.3	Robotic Ureteral Reimplant.
Chapter 53: Neurogenic Voiding Dysfunction and Functional Voiding Disorders: Evaluation and Nonsurgical Management	
53.1	Bladder Botox™ procedure.
Chapter 66: Surgical Excision of Urachal Anomalies	
66.1	Excision of urachal remnant in 15 month child using the open scarless surgical technique.
Chapter 71: Anorectal Malformations and Cloaca	
71.1	Cine rotational fluoroscopic imaging of a cloaca patient with a 3 cm common channel.
71.2	Cine rotational fluoroscopic imaging of a cloaca patient with a 3.5 cm common channel.

71.3	Cine rotational fluoroscopic imaging of a cloaca patient with a 4 cm common channel.
71.4	Cine rotational fluoroscopic imaging of a cloaca patient with a 5 cm common channel.
71.5	Cine rotational fluoroscopic imaging of a cloaca patient with a less than 2 cm common channel.

Chapter 75: Abnormalities of the Penis and Scrotum

75.1	Laparoscopic ligation for correction of varicocele.

Chapter 78: Minimally Invasive Management of Inguinal Hernias

78.1	Transperitoneal laparoscopic inguinal hernia repair in a female infant.
78.2	Standard transperitoneal laparoscopic inguinal hernia repair.
78.3	One-trocar laparoscopic-assisted extracorporeal hernia closure.

Chapter 79: Cryptorchidism

79.1	Untitled.

VIDEO ATLAS BY PIPPI LA SALLE

No.	Title

I—Bladder Surgery

I.1	Bladder neck–Pippi technique.
I.2	Bladder exstrophy variant.
I.3	BN injection after PS procedure.
I.4	Female bladder exstrophy.
I.5	Male bladder exstrophy.
I.6	Open excision of urachal cyst.
I.7	Redo bladder exstrophy.
I.8	Uretocelectomy and right ureteral reimplantation.

II—Female Genitalia

II.1	Cloacal anomaly in female with prune belly syndrome.
II.2	Female epispadias.
II.3	Female epispadias perineal (converted).
II.4	Feminizing genitoplasty.

III—Kidney Surgery

III.1	Dismembered reductive pyeloplasty.
III.2	Excision of Wilms tumor.
III.3	Left open partial nephrectomy.
III.4	Open partial nephrectomy.

IV—Male Genitalia

IV.1	Correction of primary peno-public epispadias.
IV.2	Correction of peno-pubic epispadias (post-exstrophy).
IV.3	Penoplasty for buried penis.
IV.4	1st stage hypospadias repair with preputial graft.
IV.5	2nd stage hypospadias repair with bilateral orchiopexies & lipectomy.
IV.6	Dorsal inlay tip repair & right orchidopexy.
IV.7	Hypospadias redo using dorsal inlay TIP.
IV.8	Hypospadias redo with buccal mucosa.
IV.9	Hypospadias with preputial inlay TIP.
IV.10	Tubularized incised urethral plate (TIP repair).

IV.11	Inguinal orchiopexy.
IV.12	Complete urethral duplication alternative approach for penile and ventral urethra.
IV.13	ASTRA for urethral duplication.

V—Transplantation

V.1	Kidney transplant.
V.2	Left renal auto-transplant and right aorto-renal bypass.

VI—Ureteral Surgery

VI.1	Left tapered ureteral reimplant.
VI.2	Left extravesical ureteral plication and reimplantation.

Preface

We are honored to again have the opportunity to edit the Sixth Edition of the "Kelalis, King and Belman," the standard text in Pediatric Urology for four decades. The title of the Fifth Edition was changed to *The Kelalis–King–Belman Textbook of Clinical Pediatric Urology* to commemorate the original editors. Our great friends and mentors Barry Belman and Lowell King were very helpful in orienting us to the prior edition. We are saddened at the loss since then of Dr. King, who with the late Panayotis Kelalis cannot see the current fruits of their original vision. We hope that the current text continues to build on that vision in ways that would make them proud.

The specialty of pediatric urology continues to change rapidly, and we hope that the new format of the text, with an emphasis on web-based resources, will reflect that. Much open surgery that was transitioned to laparoscopic or endoscopic surgery is now approached using the surgical robot. Availability of "big data" that crosses institutions, states and nations is allowing sophisticated health services researchers in our field to understand trends, identify risk factors, and provide advice for new pathways of care. This provides the potential to get the right care only to those who need it, increasing effectiveness and decreasing cost. Advances in understanding of hormone receptor signaling and urothelial-mesenchymal interactions are suggesting new forms of preventive therapy for developmental anomalies in the future. Emergence of population health thinking is forcing us to reconsider the ways that we evaluate and treat common conditions, such as urinary tract infection and prenatally detected hydronephrosis. In short, our field is beginning to look rather sophisticated.

We kept the general organization of the prior edition, starting with chapters of general interest, and then proceeding through each of the systems or anatomical areas of interest to urologists, and including chapters on basic science research to point the way to future clinical applications. New to this edition, and nearly unique in scope, we have added a video-based surgical atlas, edited by Joao Luiz Pippi Salle, which can be viewed as a stand-alone compendium or linked from the individual chapters. As in the prior edition, we are indebted to our returning authors and to our many new authors who have infused the text with their energetic contributions.

The text will again be accompanied by a study guide. We hope that this will prove helpful to urology and pediatric urology trainees, but also to all of us who need to prepare for certification or recertification examinations in Pediatric Urology—a subspecialty certification that was only in the planning stages when our last Edition was published. We would like to thank the authors and editors for contributing to these questions, which add significant effort above and beyond completing a chapter.

As always, this is intended as a reference work, but not necessarily the last word. We have tried to present controversy where it exists, but in the end all recommendations are made based on the experience and best belief of the authors. The authors have been chosen in every case for their expertise, experience and rationality. Although we, as editors, may not have agreed with everything our authors have stated, we consider each of them a master in their area, and have tried to minimize our influence on their message.

The change that has had the most profound impact on the Sixth Edition is the addition of a group of editors to the team who represent the best and brightest in Pediatric Urology. These are the individuals who worked directly with the authors, primarily edited the manuscripts, chased down the videos and assured appropriate formatting, and dealt with the many technical potholes that characterized this long journey. Our hats are off to Drs. Austin, Coplen, Copp, Herndon, Lorenzo, Merguerian, Ost, Park, Pohl, and Shukla, without whose efforts this book does not exist.

We are especially indebted to our publisher, Ms. Miranda Bromage of Taylor & Francis, who picked up the pieces of a technical disaster, and with the able help of Cherry Allen reassembled this complicated project from beginning to end to make it something better than it would have been in the first place. We also thank Kyle Meyer at CRC Press/Taylor & Francis and Nick Barber at Nova Techset for their professional work on this book.

Editors

Dr. Steven G. Docimo, MD, MMM, earned his MD from the Johns Hopkins University School of Medicine, trained in general surgery and urology at Naval Hospital, Bethesda, Georgetown University, and the Harvard Program in Urology at the Brigham and Women's Hospital, and completed an AUA Scholars Research Fellowship in the Department of Urology at the Children's Hospital, Boston. He completed pediatric urology training at the Johns Hopkins School of Medicine, where he remained on faculty and was named Professor with Tenure. He was later chief of the Division of Pediatric Urology at the University of Pittsburgh School of Medicine for 11 years and founded the Pittsburgh pediatric urology fellowship program. He served as chief medical officer for the Children's Hospital of Pittsburgh of UPMC (University of Pittsburgh Medical Center), a position he held for more than 10 years, while also serving as vice president for Pediatric Subspecialty Services within the University of Pittsburgh Physicians, and President of Children's Community Pediatrics. He is currently senior vice president, Clinical Operations for National Relationships for the Children's Hospital of Philadelphia. He has authored more than 300 papers, abstracts, videos, books, and book chapters.

Douglas A. Canning, MD, is chief of the Division of Urology at Children's Hospital of Philadelphia and a professor of urology in surgery at the Perelman School of Medicine at the University of Pennsylvania. He holds the Leonard and Madlyn Abramson endowed chair in pediatric urology.

Dr. Canning earned his medical degree from Dartmouth Medical School. He completed his general urological residency training at the National Naval Medical Center in Bethesda, Maryland. He then completed his pediatric urological fellowship training at The James B. Brady Urological Institute at the Johns Hopkins Hospital. Following a four-year military tour during which he was director of pediatric urology at the Naval Medical Center, San Diego, he returned to the east coast and joined the urology staff at CHOP in 1992. In 1997, Dr. Canning was appointed director of the Division of Urology at CHOP. Shortly after his appointment, he was named to the Leonard and Madlyn Abramson chair in pediatric urologic research.

He is author or coauthor of more than 100 peer-reviewed publications, three textbooks, and more than 500 editorials in urology. He is a member of the Urological Survey Editorial Committee for the *Journal of Urology*. He is an internationally recognized expert in all areas of pediatric reconstructive urology with a particular interest in the care of children with complex urological conditions such as bladder and cloacal exstrophy, hypospadias, posterior urethral valves and genital anomalies in both sexes.

Dr. Antoine Khoury, MD, FRCSC, FAAP, is the chief of pediatric urology and, with more than 25 years of experience, leads the CHOC (Community Housing Opportunities Corporation) Children's Urology Center. He is a professor of urology at University of California, Irvine (UCI) and the Walter R. Schmid endowed chair in pediatric urology at UCI.

Dr. Khoury completed his residency training at the University of Toronto and did his fellowship training in pediatric urology at The Hospital for Sick Children in Toronto, under Dr. B. Churchill. Dr. Khoury has also spent time at the University of Calgary carrying out research in infection and biomaterials. His work there resulted in several publications and a patent award on the bioelectric mechanism to eliminate bacterial biofilms. He then joined the faculty of the division of urology at the Hospital for Sick Children in Toronto and was the division head from 1995 to 2008 before coming to CHOC Children's Urology Center.

Dr. Khoury has published more than 200 peer-reviewed publications and 60 book chapters. He has delivered over 160 lectures as a visiting professor or invited speaker at both international and national levels.

Dr. Joao Luiz Pippi Salle is the division chief of urology at Sidra Medical and Research Center in Doha, Qatar. He was the former chief of urology of the Montreal Children's Hospital as well as at the Toronto Sick Kids Hospital, in Canada. He was the inaugural chair of urology and regenerative medicine at Sick Kids Hospital, University of Toronto. Dr. Pippi Salle is a pediatric urologist with special interest in genito-urinary reconstruction. He is an innovative surgeon who developed new techniques for the correction of urinary incontinence, differences of sex development, exstrophy/epispadias complex, and hypospadias. He published numerous papers and book chapters and has been a visiting professor in 35 countries. He is dedicated to teaching having completed the Education Scholarship Program and served as the director of Continued Medical Education in the Department of Surgery at the University of Toronto. Dr. Pippi Salle is also committed to International teaching in several countries where he developed several successful workshops in reconstructive pediatric urology.

Evaluation of the Pediatric Urologic Patient

Taylor & Francis
Taylor & Francis Group
http://taylorandfrancis.com

CHAPTER 1

History and Physical Examination of the Child

Anton Wintner and T. Ernesto Figueroa

HISTORY

General Considerations

The path to caring for a patient and offering a solution to a medical condition begins with a thorough medical history, and subsequent physical examination. These are the most basic elements in medical care, and when properly conducted, they allow for understanding and appreciation of the medical condition, and the ability to initiate appropriate care for the patient. The extensive progress in medical technology has given the physician new tools for the diagnosis and treatment of most medical conditions; however, no technological advance can replace the sympathetic and discriminating ear of the physician, or the gentle and perceptive hand during the physical examination. In the diagnostic process, history accounts for 80% of the information, physical examination for 15%, and special investigations for 5%.[1] A thorough history is clearly the most enlightening component of the diagnostic process.[2]

The field of pediatrics is a rather unique branch of medicine in that the medical history is usually obtained from a person other than the patient, this being the mother, the father, other relatives, or a foster parent.[3] It is important to identify the person giving the history, and to clarify the relationship to the patient. As the physician first encounters the child and the parent, it is essential to introduce oneself and offer one's services to the patient and the family. In the complex environment of modern healthcare, the family is likely to come into contact with several members of the medical team besides the pediatric urologist that they are there to see, and it can be rather confusing for the family to identify the role of each member. Many medical organizations have promoted the concept of Acknowledge–Introduce–Duration–Education–Thank you (AIDET) to encourage healthcare providers to clarify their role in the service line of the patient.[4] The accompanying adult should be asked about his or her relationship to the patient. In order to protect the patient's confidentiality and privacy, physicians have the professional obligation to define the relationship of the accompanying adult to the patient, and to determine who will be the recipient of the medical information related to the pediatric patient.[5] Current federal regulations establish limitations on the medical information that can be shared with individuals other than the patient, and there can be serious penalties for ignoring this federal directive.[6] The physician should not assume that the accompanying adult has legal custody of the child.

Upon approaching an examination room, it is important to remember that small children will often move about the room, as the family waits for the physician. Prior to entering the room, the physician should first knock gently on the door to alert the parents to pick up the child who could be sitting behind the door, and then open the door cautiously. When first encountering the child and accompanying adult, and after introducing oneself to the patient and family, it is helpful to ask what the child likes to be called, and address the child in that manner. Also, it is beneficial to find an area of interest that will show patients that we care and are interested in them, such as asking what type of play they enjoy, offering supportive commentary about their clothes, or inquiring about their interests in sports or other activities. The child should feel that they are the primary interest of the interaction, and regardless of the age, the physician should look at the child and talk to him or her in words that the child can understand at various times during the encounter. A soft and courteous tone of voice and a sympathetic look are essential in developing a trusting relationship with the child, assuring the patient and the family that the physician is concerned with his or her condition. Abrupt, pressing, and hurried interfaces often have a profoundly negative effect on the initial, and subsequent, patient–physician interactions. The physician should convey a willingness to listen, and demonstrate empathetic understanding for the information being gathered.[2] If a young child is not receptive to the interaction and is disruptive during the history taking, it is helpful to seek distraction techniques, such as a toy box, coloring books, formula or snacks, or removal from the examination room, to allow adequate history gathering. A comfortable environment can enhance communication.[3] In essence, it is important to convey to the parent the interest in the child as well as the illness.[7]

History of Present Illness

The pediatric urologic history should be tailored to the condition of the patient. Some conditions are immediately evident, such as the healthy newborn with hypospadias or undescended testis, and these require a more focused and limited approach to the history. Other conditions, such as combined diurnal and nocturnal enuresis in an older patient, are likely to require a more detailed and comprehensive assessment of the medical history. Thus, not every patient seen by a pediatric urologist will require an extensive medical history with a need to cover all the items traditionally listed in the medical history of a child. However,

the role of the pediatric urologist is to determine what key questions are necessary to formulate the most accurate description of the patient's genitourinary condition.

A good approach to history taking is to begin by asking broad-based, open-ended questions in order to ascertain the chief complaint—the main reason why the patient is in the office—in the patient's (or parent's) own words. A simple option is to begin by asking, "What brings you in today?" or "How can I help you?" This is crucial because if the patient's chief complaint is not addressed, no matter how trivial it may seem or how great the care the physician provides otherwise, the patient (and parents) will not be satisfied. For example, an adolescent patient with mild hypospadias may be more concerned with the appearance of excessive dorsal foreskin than the location of the meatus. Once a clear chief complaint is established, the physician may narrow his or her questioning to keep the patient focused and gather specific details. The patient and family should always be questioned about possible associated genitourinary symptoms, including flank pain, abdominal pain, dysuria, hematuria, incontinence, frequency and urgency, difficulty with urination, previous urologic surgery, and scrotal pain and swelling. Other symptoms, such as malaise, fever, weight loss, constipation, vomiting, or body posturing, should be reviewed as part of the history of present illness (HPI) when they are pertinent to the differential diagnosis.

Age-Related Considerations

In the evaluation of children, certain age-related, well-recognized behavioral characteristics affect how children respond to the interaction with a physician or other healthcare providers. There is an ample bibliography on this topic in the pediatric and psychological literature, but for the purposes of this chapter, the following outline of age competencies[8] can be useful to the pediatric urological care provider:

1. Infants (birth to 1 year)
   a. Characteristics
      i. Parents or primary caregivers are most important.
      ii. Sense of trust and security develop.
      iii. Fear of the unfamiliar. Stranger anxiety evident at 6–8 months.
      iv. Major source of pleasure is oral activities, such as sucking, biting, and chewing.
      v. Learns by imitation and repetition.
2. Toddlers (1–4 years)
   a. Guidelines
      i. Allow choices if possible. Prepare before a procedure.
      ii. Give one direction at a time.
   b. Characteristics
      i. Asserts independence and develops a sense of will. Has temper tantrums.
      ii. Fear of separation between 2 and 2½ years.
      iii. Learns cause and effect.
      iv. Discovers ability to explore and manipulate environment.
      v. Constructs three- to four-word sentences.
      vi. Short attention span.
3. Preschoolers (4–6 years)
   a. Guidelines
      i. Offer badge of courage (stickers) and praise.
      ii. Use dolls or puppets for explanation when performing procedures and involve child when possible.
   b. Characteristics
      i. Fears include bodily injury and mutilation, castration (males), and the dark.
      ii. Physically aggressive.
      iii. Masters and acquires new skills.
      iv. Major skill is conversation.
      v. Speaks in eight-word sentences by age 5.
      vi. Understands numbers and can count.
      vii. Questions why.
4. School age (6–12 years)
   a. Guidelines
      i. Provide privacy and explain procedures in advance using correct terminology.
      ii. Clearly define and reinforce behavior limits.
   b. Characteristics
      i. Important to belong and gain approval of peer group.
      ii. Rule-bound.
      iii. Greatest fear is loss of control.
      iv. Distinguishes between right and left side at age 7.
      v. Develops personal standards of right and wrong at age 9.
      vi. Play, simple instruction, repetition, books, visual aids, and examples are ways that an 8-year-old learns.
5. Adolescents (13–17 years)
   a. Guidelines
      i. Provide privacy and allow maintaining control.
      ii. Involve them in decision making and care.
      iii. Present them with their "rights."
      iv. Discuss virginity, prevention of sexually transmitted diseases, and pregnancy.
   b. Characteristics
      i. Development of identity.
      ii. Rapid growth of skeletal muscle mass, adipose tissue, and skin.
      iii. Common fears include loss of control, not being accepted by peers, and separation from peers.
      iv. Think they are invincible and bad things will not happen to them.
      v. May criticize parents.
      vi. Identity is threatened by hospitalization, and they are concerned with bodily changes and appearance.

Privacy and Confidentiality of the Adolescent Patient

Adolescence is a time of rapid and significant physical, emotional, and psychological change. Although the adolescent patient may represent a challenging patient for the pediatric urologist, this encounter also represents an opportunity for the urologist to educate the patient about the bodily changes (puberty), as well as about

sexuality, safe sexual practices, and sexually transmitted diseases. Many adolescents are reserved about their medical conditions, and as a group, they tend to place a greater value on peer relationships than parental or adult relationships. Gathering information from adolescents is particularly challenging, and many will not seek medical care for fear of anticipated shame and embarrassment, loss of autonomy, and fear of not being understood.[9] When facing an adolescent patient, part of the history should be obtained in the presence of a parent or guardian, but the patient should also be queried about urinary symptoms and sexual matters in a private setting. The transition from the history-gathering portion of the medical encounter to the physical examination is a good opportunity to isolate the adolescent patient from the parent to obtain additional pertinent information. Prior to proceeding with the examination, the adolescent patient should be asked if he or she prefers a private room or the presence of a parent or chaperone during the exam. Legally, minors cannot consent to medical care, so the request to examine the patient should be made in the presence of the parent. Any information obtained during this interaction should be considered confidential. There are federal guidelines regarding the confidentiality and privacy of medical information of minors, although there is variation of guidelines and privacy laws of minors from state to state.[10,11] Any healthcare provider caring for adolescent patients is encouraged to become familiar with the local (county or hospital), state, and federal guidelines regarding the privacy and confidentiality of minors, and should not hesitate to involve social services when the information poses legal and ethical ambivalence.

Past Medical History

A thorough past medical history is vital for the care of the pediatric patient. Since the history often cannot be directly solicited from the young patient, history previously recorded by another physician may be incomplete or contain inaccuracies. As such, the family should be allowed adequate opportunity to communicate their perspective of the course of events that have transpired in the life of the child. The accuracy of the past medical history is crucial because many pediatric conditions are age dependent, and therefore the physician's suspicion (and consequently the condition's position on the differential diagnosis) may depend on the age at which a particular complaint began.

The past medical history should include as much information as possible about previous hospital and emergency room visits. The patient and family should be asked about all the diagnoses that the child carries, at what age they were diagnosed, and how each diagnosis came about. Any procedures or surgeries that the child has undergone, as well as their timing, should be recorded.

The physician should ensure that the surgical history is concordant with physical exam findings, such as scars, as there is large variability among families in the degree of sophistication of their medical knowledge. This is even more important if future surgery is a possibility, and if any uncertainty arises, the previous surgeon should be consulted.

The urologist should keep in mind that many nonurological conditions may have urologic sequelae, and thus a complete understanding of the child's medical history is imperative. For example, a child may present to the urologist with new-onset hematuria, and assessment may show that the child had gastrointestinal symptoms of vomiting and diarrhea before progressing to hematuria, suggesting the possibility of hemolytic uremic syndrome. Moreover, many conditions that are not typically treated by the urologist may affect the urogenital tract, and thus may be first diagnosed by the urologist. As an example, scrotal pain and swelling may be the initial presentation of Henoch–Schönlein purpura.[12]

Prenatal History

The past medical history should include information about the prenatal history and pregnancy. The urogenital tract is the most common location for congenital malformations, many of which may be directly identified by prenatal screening. Examples include conditions such as hydronephrosis, multicystic dysplastic kidney, unilateral renal agenesis, bladder exstrophy, prune belly syndrome, posterior urethral valve, and spina bifida. Other urological conditions may be indirectly diagnosed. For example, imperforate anus (with its urological sequelae) may present with bowel calcifications on prenatal ultrasound. Still other conditions, such as congenital heart disease and Down's syndrome, may be diagnosed prenatally, raising suspicion for the urologic conditions with which they are commonly associated.

The prenatal history should also include any illness or medications to which the mother was exposed during pregnancy. Viruses and medications (both prescription and nonprescription drugs) may be teratogenic, providing insight into the etiology of some congenital anomalies.

The child's gestational age at birth should also be noted, as premature children tend to have a more complex medical history than full-term infants. Lung immaturity is also much more common in premature infants and may impact the way the child's responds to anesthesia.

Review of Systems

The review of systems (ROS) is an opportunity for the physician to ask questions about symptoms that the patient may not consider to be important, or even related to the main complaint. Yet often these symptoms are both important and related, and provide invaluable insight into the patient's condition. The ROS may also serve to ensure that the physician has not overlooked any symptoms the patient may be experiencing. The comprehensiveness of a formal ROS varies from physician to physician, but the key is to ensure that it is completed in as consistent of a manner as possible.

The ROS should begin with a few general questions about the growth and development of the child. A comprehensive developmental history is not crucial, although a general awareness about the patient's ability to reach developmental milestones is important.

Next, broad questions about heart conditions, heart murmurs, visits to cardiologists, and any pulmonary conditions, such as asthma, will help give insight into the patient's risk factors for general anesthesia.

Questions about the gastrointestinal tract are often pertinent to the urologist. Particularly in children, poor defecation habits and constipation have long been recognized to contribute to a number of urological conditions, from urinary tract infections to voiding symptoms and urinary incontinence.[13,14] The term *constipation* implies various meanings to patients and healthcare providers, and it is beneficial to define what we mean by the term *constipation*, including hard and painful defecation, and infrequent defecation of less than three bowel movements per week.[15]

General questions about the genitourinary tract and voiding should be asked of all patients presenting to the urologist, even if these questions are not directly related to the patient's chief complaint. The patient and family should be questioned about previous kidney problems, and pain in the area of the low back. The patient's voiding history should be taken, and the patient and family asked about symptoms of frequency, urgency, day and night incontinence, dysuria, and hematuria. Young male patients in particular should be questioned about their urinary stream. A double stream may indicate an accessory urethra or urethrocutaneous fistula, while a high-pressure, deflected stream with prolonged voiding time is characteristic of meatal stenosis.

Review of the neurological history of the patient should include questions about seizure history, as most first-time seizures occur in childhood. The child and family should also be questioned about dizziness and fainting, as well as any numbness, weakness, or difficulty running or playing.

Finally, the physician should screen the child for symptoms of depression and anxiety. The time around puberty is especially stressful, and this stress may be compounded in children with urological abnormalities or medical conditions in general. Children who are depressed or suffering from severe anxiety should be appropriately referred. Failure to address psychiatric concerns will likely lead to worse medical outcomes, as depressed patients are less likely to be compliant with treatment.[16]

Medications

Any previous or current medications should be documented. The physician should also note the reason for each medication, the dosage, the typical schedule, how long the child has been taking the medication, and any recent changes. The patient and family should also be asked in a delicate manner about the degree of compliance to each medicine, and whether they perceive it to be effective.

The physician should consider the possible interactions and side effects of the patient's current medications and any new medicines to be prescribed. Many medications have cholinergic or anticholinergic properties, which may affect voiding and urinary function. Particularly in children, the physician should carefully weigh the pros and cons of beginning any new medications and discuss these with the family.

In order to reduce the occurrence of medication errors and patient harm, the Joint Commission introduced the concept of "medication reconciliation" in 2006.[17] When admitting a patient to the hospital, their medication regimen should be carefully reconciled to avoid duplications and omissions. Abrupt or accidental changes in medication may not only confuse the clinical picture but also cause direct harm to the child through overdose or withdrawal. Upon discharge, the patient's preadmission medication regimen should be carefully reviewed, as some medications may have been stopped or altered at the time of admission. It is the responsibility of the discharging physician to ensure that all preadmission medications are restarted at the time of discharge, if required.

Allergies

One of the greatest dangers in starting a new medication is an allergic reaction, which in the worst case may be anaphylactic. This may be avoided in most cases with a careful allergy history, as initial exposure to a medication rarely results in life-threatening anaphylaxis. Typically, life-threatening anaphylaxis follows immune system sensitization to a particular antigen, often accompanied by an initial mild reaction. However, many children have no prior documented history of exposure, and can progress to anaphylaxis and a risk of dying from the event.[18] Patients and their family should be asked about which medicines they are allergic to, what type of reaction they have, and when they were last exposed. Patients should also be asked about nonmedicine allergies, such as shellfish and latex. Seasonal allergies rarely have direct crossover with medications, although children with seasonal allergies may be more prone to reactive airway disease. The family should be questioned about other members having allergies to medications, specifically antibiotics and penicillin.

Most young children have had little exposure to medications, and it may be that their first allergic reaction results from antibiotics used to treat or prevent a urinary tract infection. Newborn children with known urinary tract abnormalities are often placed on antibiotic prophylaxis in the first few days of life as their first medication.[19] The risk of anaphylaxis with penicillin has been estimated at 0.015%, with a fatality rate of 0.002%.[20] If a reaction does occur, the pediatric urologist or pediatrician should immediately stop the medication and document the reaction. Signs of respiratory compromise or anaphylaxis mandate emergency treatment.

Subacute Bacterial Endocarditis

Genitourinary surgery was, in the past, one of the common indications for subacute bacterial endocarditis (SBE) prophylaxis in patients with some types of congenital heart disease.

According to the 2007 American Heart Association guidelines, however, "antibiotic prophylaxis solely to prevent infective endocarditis is no longer recommended for patients who undergo a gastrointestinal or genitourinary tract procedure, including patients with the highest risk of adverse outcomes due to infective endocarditis."[21]

Despite these recommendations, the urologist may be well served to have a conversation with the child's cardiologist about the need for SBE prophylaxis, as some cardiologists may not be completely comfortable with this approach.

Family History

The importance of a detailed family history must be emphasized. Pediatric patients are young, and therefore have had much more limited environmental exposure than older individuals. This greatly increases the likelihood that a given disease has a genetic component. Examples of genetic disorders include autosomal recessive polycystic kidney disease, von Hippel–Lindau disease, and renal tubular acidosis. Even diseases that are not strictly heritable, or in which no specific genetic mutation has been identified, may have a familial tendency. Examples of such diseases include vesicoureteral reflux, urinary tract infections, voiding disorders, and hypospadias.

Gathering of the family and genetic history for urologic conditions may prove challenging for several reasons. First, many genetic disorders have incomplete penetrance, making affected individuals harder to identify. For example, a patient with moderate hypospadias may have an affected grandfather who was never diagnosed because the grandfather's hypospadias was mild and did not cause the grandfather concern. Second, urologic conditions, particularly genital disorders, are often not openly discussed, making it more difficult to identify affected relatives.

Social History

Sexual History

A sexual history should be gathered in all adolescent and preadolescent patients. The history should always be taken in a quiet, private place where the patient will be more likely to answer questions openly and honestly. A carefully presented, nonjudgmental assessment of sexual history should be part of the medical history of every pubertal patient. It is essential that the patient is allowed all latitude to feel comfortable in discussing this most personal aspect of their medical history. An introductory description from the physician explaining that this is an integral part of medical care, and that all patients go through this evaluation, may help alleviate the expected apprehension from the patient.[22]

Patients should be asked about their sexual habits (number of partners, use of contraceptives, etc.) and should be appropriately counseled about safe sex practices. Furthermore, patients should also be questioned about symptoms of sexually transmitted infection so that they may be treated appropriately if required. Patients should be asked about genital itching, sores, discharge, dyspareunia, and previous history of sexually transmitted infection. The urologist should always keep in mind that many patients with complex medical conditions, such as spina bifida, may not have the peer support groups and educational opportunities of the rest of the healthy population, and these encounters with the healthcare provider are unique opportunities to offer teaching and answers to the silent questions that many of these patients have about sexuality.[23]

Substance Use

Both the family and the child should be questioned about substance use. Most studies show that patients who are addicted to tobacco and alcohol become addicted before adulthood. Tobacco and alcohol may lead to marijuana and other drug use in adolescence and later life, and have significant morbidity in and of themselves.[24] Patients should be counseled about these dangers and offered resources for quitting if required.

Families should also be questioned about adult substance use in the home. This must be done in a gentle, nonaccusatory manner. Risks such as secondhand smoke, which are obvious to the physician, may not be obvious to some parents. If the parents express interest in quitting an addictive substance, they too should be appropriately referred.

Environmental Exposure

Families should be asked about parental vocations and living situations, as certain industrial chemicals carry health risks to both the parents and child. If these risks can be identified early on, a strategy to mitigate them may be devised. There is mounting evidence on the effect of environmental agents on the incidence of hypospadias and cryptorchidism.[25]

School and Home

As part of the social history, the child should be asked about school and his or her social environment. Does the child have friends at school? Is he or she progressing well in his or her academics or struggling to pass the current grade? Has he or she been held back a year? Asking about school not only helps build a therapeutic alliance with the child and family, but also provides insight into social and mental development.

If not already obtained during the initial interaction, an assessment of the social history should include the marital status of the parents; who cares for the children if the mother is employed; number of siblings; progress at school; recent stressful experiences, such as moving or loss of a family member; and the type of interactions with other children (play dates, sports teams, etc.). Sometimes this information may elicit a diagnostic path possibly unrelated to the initial complaint of the patient.

Medical Insurance

Children without appropriate insurance coverage should not be turned away. Many states have social programs that cover children, particularly from low-income families. If a child does not have insurance, the family should be referred to a hospital case manager or other such worker who can aid them in attaining appropriate coverage.

PHYSICAL EXAM

Approach to the Examination of the Pediatric Patient

An important component of the physical examination of the pediatric patient occurs while obtaining the medical history and observing the patients and their relationship with their family. While listening to the family, the physician can assess the level of comfort of the child and his or her overall physical health, and anticipate the approach to the physical examination. Certain behaviors, of which the child may not even be aware, may become evident during this short observation period. These behaviors can provide the physician with invaluable insight into the etiology of the chief complaint. For example, the characteristic posturing of a child, Vincent's curtsy, may point to a child's attempt to temporarily prevent incontinence due to an inability to inhibit bladder contraction[26] (Figures 1.1 and 1.2).

When the time comes for the examination, the child should be informed in simple terms that are understandable to him or her that an examination is to take place. With younger children, having the parents stand or sit next to them during the examination can help reduce the fear of the experience. Young children, less than 1 year of age, can occasionally be examined while they recline in their mother's lap. Every effort should be taken to minimize separation anxiety in these children, common in children younger than 3 years of age. Preschoolers, ages 4–6 years, fear the possibility of bodily injury and mutilation, possibly castration, so the genital examination usually produces significant anxiety in this age group. In older children, and adolescents, privacy is very important, and respecting that privacy during the examination is vital, by asking the family members to look aside or to step out of the room. Examination of the adolescent should always be handled with sensitivity to avoid unnecessary embarrassment and preserve the dignity of the patient.[27]

Prior to placing hands on the patient, the examining physician should wash his or her hands, and repeat the hygiene practice at the end of the examination. A cold pair of hands can tense the patient unexpectedly. The physician owes the patient the courtesy of a warm pair of hands during the examination.[27]

Upon placing the patient on the examining table, the pediatric urologist can determine if the child will cooperate with the examination. In a cooperative child, the physical exam should be as thorough as possible, as there is no guarantee that the child will remain cooperative at future appointments. If the child remains cooperative, the various abnormalities identified during the examination should be demonstrated to the parents as part of their education into the child's urologic condition.

FIGURE 1.2 Vincent's curtsy.

Age-Pertinent Factors

1. The uncooperative child and toddler
   a. When the child is uncooperative, the physician may rely on distraction techniques, such as allowing him or her to play with a penlight or toys or hold an otoscope, to console the child. It is noteworthy that many patients who are uncooperative probably have had a negative experience with a healthcare provider in the past. If the child remains uncooperative or fearful, one should try to make the best of the situation, but never force an examination on the combative child. If an acute surgical condition is suspected, and the child is uncooperative, persevering with the examination with the use of assistants to gently restrain the combative child may be necessary. A useful technique to examine the abdomen and genitalia of anxious young children is to have the mother embrace, and gently pin down, the upper torso of the child against the examination table, while an assistant places the palms of their hands on the patient's thighs, at midthigh, to keep the body in place against the examination table. The mother's body shields this child's head from the examination. This allows the examining physician to conduct a quick and effective examination while the child is reassured by the closeness to the mother.
2. The role of the chaperone
   a. The examination of the pediatric patient, whether an infant, toddler, child, or adolescent, should always be performed in the presence of a parent or guardian. In situations when the parent or guardian is not available, or when their presence may be detrimental to the patient, the presence of a chaperone as an adult member of the healthcare team should be offered to all pediatric patients undergoing potentially embarrassing or psychologically stressful examination, such as examination of the anogenital areas, reproductive organs, or breast of the adolescent female. The role of the chaperone is to "reinforce the professional nature of the interaction and content of the examination and to provide a witness in case of misunderstanding."[28] The American Academy of Pediatrics updated its policy on use of a chaperone for pediatric patients in 2011.[29]

Vital Signs

Importance of Vital Signs

A patient's vital signs are the most basic and broadly applied component of the physical exam. The four basic vital signs are heart rate, respiratory rate, temperature, and blood pressure. These signs provide a wealth of information about both the acuity of the patient's condition and its etiology. Vital signs are particularly useful because they can be followed over time, allowing a dynamic view of the course of the patient's illness. Due to their objectivity and quantitative nature, they have lower interobserver variability than many other physical exam findings, making them useful in situations in which the physician must assume care of a patient with whom he or she is not familiar—a scenario ever more common with today's resident work hour restrictions and handoffs.[30,31] Vital signs are often the deciding factor in what is perhaps the physician's most important decision—whether it is safe to send the patient home.[32]

Despite the immense value of vital signs, in a world where physicians are asked to do more in less time, the responsibility for taking vital signs often falls on other healthcare professionals, techs, or medical assistants with varying degrees of medical knowledge. Ultimately, therefore, if the physician cannot take vital signs himself or herself, he or she should ensure that the vital signs are congruent with the patient's history and other clinical findings. If any doubt arises as to the reliability of the patient's vital signs, they should be repeated.

Temperature

The median temperature in the adult population is 98.6°F, and fever is generally considered to be a temperature of >100.6°F when it is consistent with other clinical findings. Unlike other vital signs, these figures are not significantly different in the pediatric population, although the variation in normal temperature may be greater in children than in adults.

In newborn infants, the nervous system is not yet fully myelinated, limiting their ability to effectively regulate and respond to changes in core body temperature and resulting in larger temperature shifts than might be expected in other patients. Moreover, newborns do not have the ability to shiver as do older children and adults, but must rely on the metabolism in order to increase their core body temperature. Infants also struggle with thermoregulation because their ratio of surface area to mass is more than three times that of a normal adult, making them more susceptible to temperature changes in their ambient environment. For example, a newborn may present with an above-average temperature swaddled by his or her mother in a blanket, while showing a lower-than-normal temperature after lying undressed in an air-conditioned exam room for several minutes.

When considering a patient's temperature, particularly when considering short-term trends or multiple temperature readings taken close together, it is important to ensure that all temperatures were taken by the same modality (oral, rectal, tympanic, etc.).

Rectal temperature is the most reliable measure of core body temperature since it is least influenced by the ambient temperature. It is especially ideal in small children, who may have difficulty holding an oral thermometer in their mouth for the full 60 seconds that is generally required for an accurate reading. In general, oral temperatures tend to be approximately 1°F lower than rectal temperatures. This difference may be exaggerated by recent ingestion of cold substances, such as popsicles, or with an increase in respiratory rate. Thus, the physician must be aware that a tachypneic patient with a normal oral temperature may actually be febrile by rectal temperature.

Other common modalities for measuring temperature include tympanic membrane, temporal artery, and axillary. Tympanic membrane temperatures may more accurately reflect core body temperature than do oral

temperature measurements, but just like oral temperature measurements, they may at times be volatile. Obstruction of the tympanic membrane by a foreign body or, more commonly, cerumen may artificially decrease tympanic membrane temperature readings.[33]

The accuracy of temporal artery core temperatures correlates well with rectal temperature in determining fever in pediatric patients, but is less invasive and thus causes less discomfort. This modality has been extended to premature infants in the neonatal intensive care unit (NICU) setting, with the variation of placing the probe on the neck behind the ears.[34]

Lastly, axillary temperatures, although popular in the lay population, are inaccurate and should be used on a very limited basis by healthcare providers.

Heart Rate

Normal heart rate can vary widely in the pediatric population, depending on age. Normal heart rate can range from 55 bpm in the teenager to 170 bpm in a premature infant. It is therefore crucial for the pediatric urologist to consider the age of the child when analyzing heart rate.

The two main causes of tachycardia in a pediatric outpatient setting are infection and physical activity (such as a fussy or crying infant, hyperactive toddler, or anxious child). Increased sympathetic stimulation resulting from fear or medication (e.g., stimulants) may also increase heart rate. Likewise, medications such as anticholinergics may limit the ability to increase heart rate, thus masking a potential infection.

The most common location for taking a patient's pulse is the radial artery, and this is usually done by counting the beats in a 10-second period and then multiplying this figure by 6 to get the beats per minute. Alternatively, in infants and small children, where the radial pulse may be difficult to palpate, a carotid or femoral pulse may be taken instead.

Blood Pressure

Blood pressure also varies with age, although unlike the heart rate, this relationship is positively correlated with age. It is difficult to precisely define the normal blood pressure range at a given age due to differences in the rate of development. Therefore, small deviations from the expected range for a given age are usually not as significant as deviation from previous blood pressure patterns of a particular patient.

When measuring blood pressure in pediatric patients, it is crucial to use an appropriately sized cuff. A cuff that is too large will result in an artificially low blood pressure, while a cuff that is too small will result in an overestimate. Artificially low blood pressure readings can also occur due to excessive pressure with the stethoscope by the examiner, resulting in a tamponade effect on the brachial artery. This is particularly important in pediatric patients, whose blood pressures tend to be lower than those of the adult population, requiring a gentler touch.

Respiratory Rate

Similar to heart rate, the respiratory rate decreases with age, approaching an adult rate of 12–18 breaths per minute near the time of puberty. Respiratory rate may be increased by exercise or fussiness in the pediatric patient, but should return to normal within several minutes of cessation of physical activity. A persistently elevated respiratory rate with normal heart rate and blood pressure may be a sign of respiratory compensation for a metabolic acidosis, while a decreased respiratory rate may compensate for a metabolic alkalosis. Increased respiratory rate combined with increased heart rate and decreased blood pressure may be a sign of hypovolemic or septic shock. Most ominous, however, is the finding of a child with increased work of breathing and accessory muscle use, as this may signal impending respiratory failure.

Examination of the Chest, Breast, and Axilla

Examination of the Chest

As part of the physical exam, the pediatric urologist should auscultate the heart and lungs. Although this may only rarely produce novel findings, it is particularly pertinent in patients with a known cardiac anomaly or in patients with syndromic findings. It is also important in evaluating a patient's readiness for surgery, as heart conditions, thoracic cage abnormalities, or respiratory compromise may predispose the patient to anesthetic complications.

Clinical Breast Exam and Gynecomastia

In evaluating the development of a pediatric patient, the breast and axilla should be examined, as they provide key information about the effect of sex hormones on the patient's development. In the adult population, a clinical breast exam is conducted mainly on females, for the purpose of screening for breast cancer. In the pediatric population, however, a breast exam should be conducted on both males and female.

In males, the aim of the breast exam is to evaluate for gynecomastia. Gynecomastia is characterized by ductal proliferation. It is common in neonates due to an excess of maternal estrogens, in adolescents due to an imbalance in the production of estrogens or androgens, and in obese children due to excessive peripheral conversion of steroids to estrogens by adipose tissue aromatase. Pathologic conditions associated with gynecomastia include estrogen-producing adrenal gland and germ cell tumors, diabetes, and hyperthyroidism. It may also be caused by some medications.

In females, the clinical breast exam is most useful for evaluating sexual development (Tanner stage). Thelarche is the first sign of puberty in the female. It occurs, on average, between 9 and 10 years of age, and begins with elevation of the papilla (see "Growth, Development, and Tanner Stage" for complete Tanner staging). Adrenarche, the onset of androgen-dependent development of axillary hair, follows thelarche.

In pediatric female patients without a specific complaint, the clinical breast exam may be limited to inspection for the purpose of defining the developmental stage. If a gross abnormality of the breast is visible, palpation may be required, and should proceed in a manner similar

to that used in adults. Prior to beginning palpation, the procedure should be explained and permission should be asked of both the parent and the child.

In the pediatric male patient in whom gynecomastia is a concern, the breast exam should begin with inspection, although palpation is always required. This is because true gynecomastia must be distinguished from pseudogynecomastia. In true gynecomastia, breast enlargement occurs as a result of glandular and epithelial proliferation of breast tissue due to the effect of excess estrogen. In pseudogynecomastia, however, breast enlargement is purely the result of increased adipose tissue. Therefore, if true breast tissue cannot be palpated, then gynecomastia cannot be diagnosed no matter the size of the breast.[32]

Examination of the Axilla

In the pediatric patient, the axillary exam consists of inspection and palpation. Inspection of the axilla is useful for establishing the type and density of axillary hair in determining the Tanner stage. Axillary hair in a young patient may be the first sign of precocious puberty.

Unlike in adults, in whom nontender axillary lymphadenopathy may signify breast cancer, nontender axillary lymphadenopathy in childhood is both common and generally benign. It may, however, be associated with lymphoproliferative disorders and may require further investigation based on history.

Growth, Development, and Tanner Stage

Growth and Development in the Infant and Child

A newborn infant will lose a portion of his or her body weight over the first few days of life, but is expected to return to birth weight by 2 weeks of age. After this initial weight loss, a weight gain of 30 g (1 oz.)/day is expected during the first 3 months of life, 20 g/day between 3 and 6 months, and 10 g/day between 6 months and 1 year. The daily rate of growth continues (as a percent of body mass) to decline until adolescence, when individuals undergo a growth spurt.

During well-child exams, pediatricians monitor child growth using standardized growth curves indicating "normal" values for 95% of children at a given age (specialized growth charts are also available for children with certain genetic disorders, such as Down's syndrome). Failure to thrive is a condition in which a child is not gaining as much weight as expected and is defined by the crossing of two major percentile lines (e.g., 90th percentile, 75th percentile, etc.) on the National Health Statistics Growth Chart.[33] Usually, weight is affected before height. Although most failure to thrive is caused by inadequate caloric intake or absorption, it may also be caused by systemic conditions. In addition to malignancy, urological conditions that may cause failure to thrive include recurrent urinary tract infections, chronic renal failure secondary to obstructive uropathy, renal tubular acidosis, or Fanconi syndrome.

In conjunction with growth pattern, the pediatric urologist should also make a note of the motor and cognitive development of the patient. Delayed milestones in these areas may be the result of central nervous system (CNS) injury or spinal cord dysfunction and may therefore have profound effects on urinary function, specifically dysfunctional voiding. Moreover, a child with delayed language skills may be referred to the urologist out of concern for daytime wetting when in fact the child may not yet be developmentally ready for toilet training.

Growth and Development of the Adolescent

Adolescence is a period of both rapid physical growth and sexual development. During the adolescent growth spurt, children gain as much as half of their adult weight and a quarter of their adult height. The growth spurt lasts 2–3 years and occurs 1–2 years earlier in females than in males.

True puberty is defined as the time during which the hypothalamic–pituitary axis matures, leading to an increase in luteinizing hormone (LH), follicle-stimulating hormone (FSH), and gonadal sex steroids (estrogen and testosterone). It is preceded by adrenarche—the onset of adrenal steroid synthesis—by 2 years.

In males, testicular enlargement is the first sign of puberty and occurs between 11 and 12 years of age. The growth of pubic hair occurs next and is followed by growth of facial or axillary hair 2 years later.

In females, puberty begins with thelarche (the development of breast buds) between 9 and 10 years of age. It is followed by pubic hair growth, and finally menarche between 12 and 13 years of age.

Tanner staging serves as a metric for monitoring the development of pubertal growth and sexual maturation. This staging system or scale is named after the British pediatric endocrinologist Dr. James M. Tanner, who examined a group of females every 3 months over two decades as a longitudinal study of pubertal growth. He went on to categorize these patients into five stages that represent a continuum of pubertal growth.[35] Tanner stages for both males and females are routinely used to assess normal and abnormal pubertal growth.[36] The Tanner stages as a classification of sexual progression define the changes of the external genital development in boys, breast development in girls, and pubic hair appearance in both boys and girls. The charting of these changes has been replicated in many references, and essentially can be summarized as follows:

Genital development (boys)

- *Stage I*: Prepubertal
- *Stage II*: Testes and scrotum enlarge and scrotal skin becomes thicker
- *Stage III*: Enlargement (elongation) of penis and further testicular growth
- *Stage IV*: Darker skin, increase in girth of glans and penis, continued growth of scrotum and testes
- *Stage V*: Adult genitalia

Breast development (girls)

- *Stage I*: Prepubertal
- *Stage II*: Elevation of breast and papilla (nipple) to produce a breast bud
- *Stage III*: Continued enlargement of the breast and areola with a smooth contour

- *Stage IV*: Papilla and areola form a secondary mound above the level of the breast
- *Stage V*: Adult stage with projection of papilla and recession of areola

Pubic hair (boys and girls)

- *Stage I*: Prepubertal (if hair is present, it is similar to abdominal wall hair)
- *Stage II*: Sparse appearance of pigmented hair, straight or curled; first noted at base of penis or along labia majora
- *Stage III*: Hair pattern is darker and curled, coarser, migrating to skin overlying symphysis pubis
- *Stage IV*: Hair is similar to adult distribution but in a slightly smaller area than for the adult
- *Stage V*: Adult hair distribution, more abundant

Abdominal Exam

General Abdominal Exam

Thorough examination of the abdomen requires inspection, palpation, and auscultation. In the abdomen, auscultation should always precede palpation, as palpation may decrease the tone of the bowel loops, resulting in decreased bowel sounds. Secondly, palpation of the abdomen is more irritating than auscultation, and in cases where the abdomen is acutely tender, the patient is more likely to decline further examination following palpation, rendering the abdominal exam incomplete. Detection of an abdominal mass may be the first manifestation of a pathologic or nonpathologic process, such as a distended bladder, a multicystic dysplastic kidney, a hydronephrotic kidney, or Wilms' tumor.[37]

When inspecting the abdomen, the physician should note both the contour of the abdominal wall and any skin markings. A scaphoid abdominal contour may indicate malnutrition or cachexia (malignancy), while a localized protuberance of the abdominal wall generally indicates distention of one or more intra-abdominal organs. For example, a protuberance in the hypogastrium may indicate distention of pelvic organs, such as the bladder (outlet obstruction or dysfunctional voiding). In infants or small children, a localized abdominal protuberance may also be the result of a solid tumor, such as neuroblastoma or Wilms' tumor.

In children with a history of constipation, urinary tract infection, or dysfunctional voiding, the abdomen should be palpated for hardened stool. Stool is most easily palpable in the left lower quadrant (sigmoid colon), although it may be palpable throughout the abdomen.

Normal-sized healthy kidneys are difficult to palpate in older children and teenagers because they are overlapped by the diaphragm and ribs and covered by thick musculature of the abdomen and back. In younger children, the kidneys may be palpable on deep inspiration, particularly on the right, where the kidney sits approximately one vertebral level lower (L1-L4 vs. T12-L3 on the left) due to the presence of the liver during development. Palpation of the kidney is best achieved with a bimanual technique, asking the patient to inhale and exhale deeply while progressively applying deeper palpation in the subcostal areas.

FIGURE 1.3 Abdominal mass.

In neonates and small infants, it is possible to use a single-handed technique by grasping the patient's flank between the thumb (anteriorly) and fingers (posteriorly over the costovertebral angle). At the point of deepest inspiration, bring the thumb in opposition with the fingers, trapping the kidney in between.

In children, over half of the palpable abdominal masses are of renal origin (Figure 1.3). A solid and therefore potentially malignant mass (Wilms' tumor or neuroblastoma) may be occasionally distinguished from a cystic mass (hydronephrosis, polycystic kidney disease, or multicystic kidney disease) by transillumination. This can be accomplished by placing a flashlight against the costovertebral angle on the side of the mass and examining the anterior of the abdomen. Since cystic masses are filled with fluid, they scatter light rays and appear to glow. Solid masses are opaque and will prevent transmission of light. Transillumination is most reliable in younger infants and newborns, as skin thickness, and as a result opacity, increases with age.

With regard to the physical examination of pediatric malignant masses, neuroblastoma typically presents as a firm, irregular mass, which crosses the midline due to its propensity for dissemination and multiple potential sites of origin. Conversely, Wilms' tumor typically presents as a mobile abdominal and flank mass, which does not cross the midline.

In patients with symptoms of urinary tract infection, pyelonephritis should be ruled out. Pyelonephritis, or any condition that distends the renal capsule (stone, perinephrenic abscess, etc.), will cause tenderness at the costovertebral angle.

Examination of the Bladder

The bladder is amenable to examination by both palpation and percussion. Palpation of the bladder should begin at the umbilicus and move caudally toward the symphysis pubis. The bladder is rarely palpable in most patients. A palpable bladder may be soft or tense, depending on its volume and also on the thickness of the detrusor muscle. The finding of bladder distension should prompt further evaluation for bladder outlet obstruction, neuropathic bladder, incomplete bladder emptying, or urinary retention (Figure 1.4).

FIGURE 1.4 Palpation of distended bladder.

Significant bladder distension may be visible even on inspection as convex protuberance in the hypogastric region. If bladder distension is suspected based on physical exam, additional evaluation with ultrasound is warranted.

Genital Examination

Importance of the Genital Exam

The genital exam is not only the specific domain of the pediatric urologist, whose expertise in examining this area surpasses that of any other specialist, but also a part of the physical exam that is conducted less frequently by the generalist due to its intimate nature. Therefore, missed diagnoses in this area can go unnoticed for longer periods of time than other more readily accessible physical areas. In addition, many genital issues are congenital in origin and best repaired when the child is young. Finally, some genital conditions (undescended testes and disorders of sexual differentiation), whether repaired early or not, may have a significant medical and psychosocial effect on the patient later in life if they go undiagnosed.

Examination of the Scrotum and Its Contents

Examination of the scrotum begins, like other areas of the body, with inspection. Inspection may not only identify rare congenital malformations, such as disorders of sexual differentiation, but also provide insight into more common conditions. The inguinal and scrotal areas can be assessed simultaneously, looking for asymmetry, hernias, hydroceles, and undescended testes. Hydroceles should be closely examined to ensure that the testes can be palpated. Transillumination is frequently performed to demonstrate a fluid-filled hydrocele sac (Figure 1.5). Failure to identify a testis by palpation in a patient with a tense hydrocele should always prompt further evaluation with a scrotal ultrasound regardless of the results of transillumination, but particularly when transillumination suggests a solid mass[38] (Figure 1.6). The position of the testes in the scrotum should be observed prior to touching the patient, and invariably descended and retractile testes will be visible prior to palpation. Placing a hand over the inguinal area at the pubic tubercle before touching the scrotum will prevent

FIGURE 1.5 Transillumination of a scrotal hydrocele.

a retractile testis from ascending into the inguinal area in response to the cremasteric reflex, and allow the examiner to distinguish a retractile from an undescended testis (UDT) (Figure 1.7a and b). The examination of the scrotal contents

FIGURE 1.6 Testicular mass.

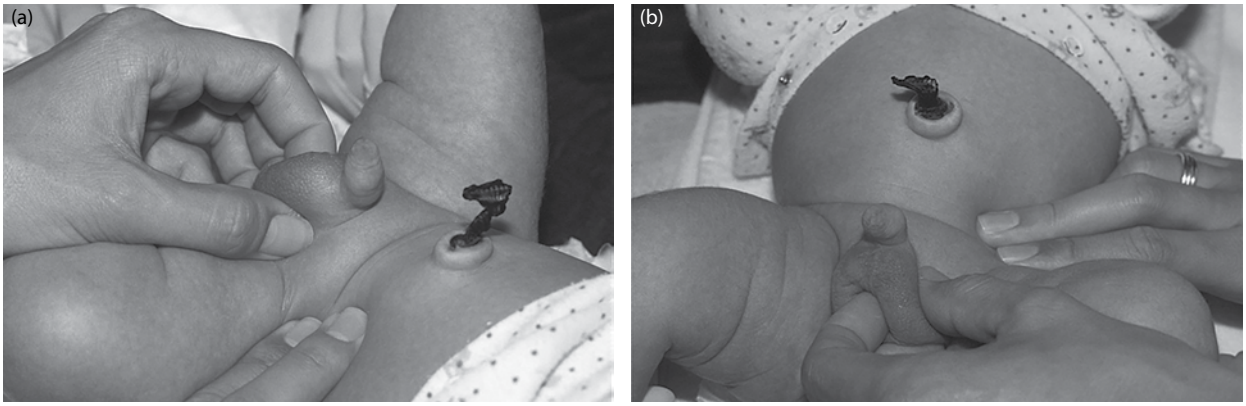

FIGURE 1.7 Two-handed examination for undescended testis (UDT).

should be performed during each visit despite the findings of scrotal testes on an earlier visit, to exclude the possibility of testicular ascent.[39] When examining a child for an undescended testis, gliding the soap-lubricated examining fingers over the child's inguinal area will often reveal the location of the testis, allowing the examiner to distinguish a palpable undescended testis from a nonpalpable testis. As the boy reaches adolescence, the first sign of puberty is the growth of the testes, which usually occurs around 11–12 years of age, corresponding to Tanner stage II.

During the examination of the scrotal contents, it is important to determine if the testes are symmetrical in size and appropriate for age and Tanner stage, as well as the consistency of the testes. Variations in size and consistency may point toward the presence of abnormalities, such as a testicular tumor, a clinically significant varicocele, atrophic testis in a patient with a previous orchiopexy or hernia repair, dysgenetic testes, vanishing testis syndrome, XX male syndrome, fragile X syndrome, precocious puberty, delayed puberty, and congenital adrenal hyperplasia.

As part of the examination, it is valuable to gauge the size of the testes. There are two distinct commercially available orchidometers that can be used to estimate testicular volume, and the examiner should ideally have these measuring tools available during the genital examination of the male patient (Figures 1.8 and 1.9). In the absence of these tools, a plastic ruler or a tissue caliper can offer some sense of testicular size (Figure 1.10). The most popular orchidometer is the Prader orchidometer, first popularized by Dr. Andrea Prader in 1966.[40] This orchidometer consists of a string holding a group of 12 oval beads graduated from 1 to 25 cc that are used to match the size of the patient's testis to estimate testicular volume (Figure 1.8). Another type of orchidometer, the Rochester orchidometer, consists of a number of elliptical "rings" through which the testis is placed to estimate volume[41] (Figure 1.9). Both of these devices can provide a general estimation of volume and symmetry during the exam. Any abnormalities detected during the examination should prompt a more precise and accurate assessment of testicular volumes with scrotal sonography, which has been shown to be superior in the assessment of testicular volume than either the Prader or Rochester orchidometer.[42–44] Paltiel and collaborators compared various formulas to estimate testicular volume based on sonographic measurements in a canine model, and they determined the Lambert formula, first described in 1951 (Length × Width × Height × 0.71), to be the most accurate and reliable.[43,45] The formula for a prolate ellipsoid ($\pi/6 \times$ Length × Width × Height) also has been used to calculate testicular volume based on sonographic measurements.[46] These formulas and estimation of volume can be useful to the clinician to follow testicular growth and

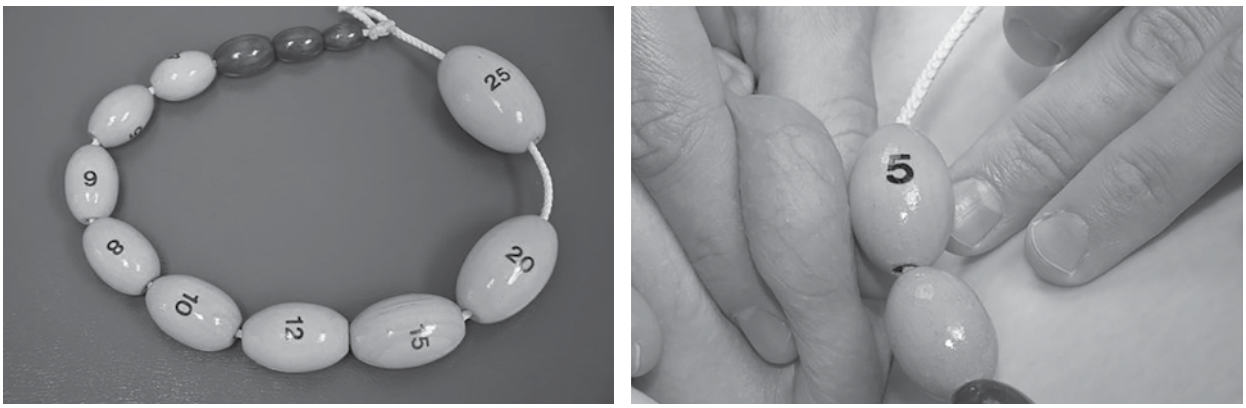

FIGURE 1.8 Prader orchidometer being used (right panel) to measure the testis volume by comparison with elliptical beads of varying sizes.

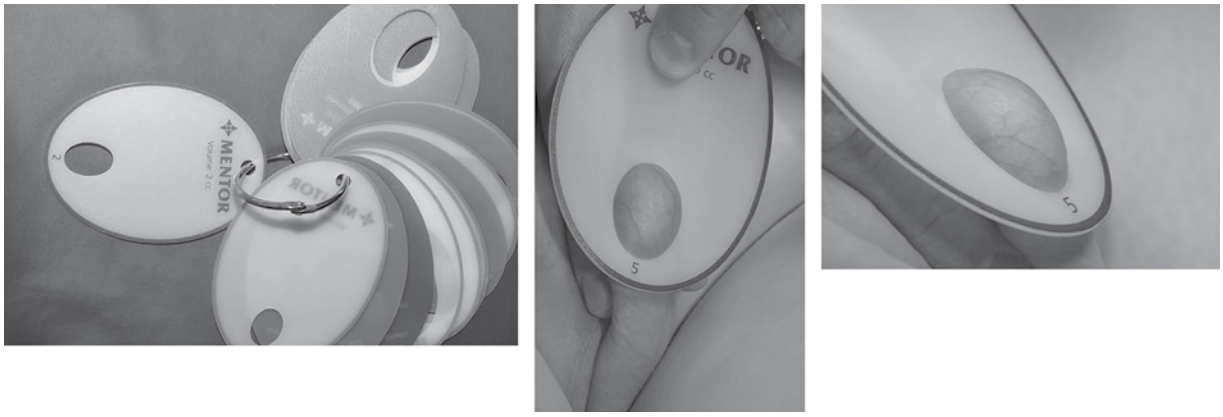

FIGURE 1.9 Rochester orchidometer being used in right upper and lower panels to measure the volume of the testis by placement of the testis through the opening.

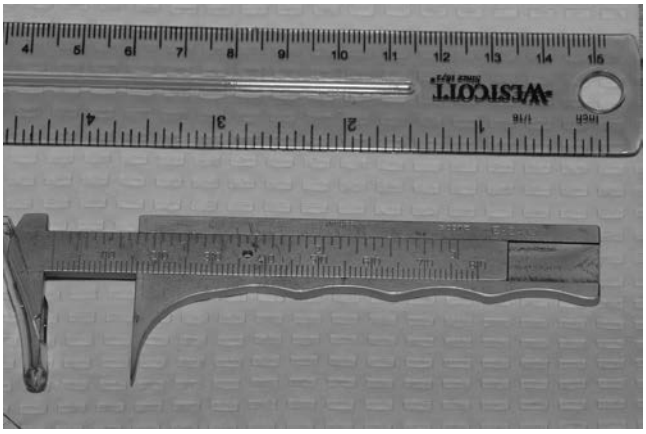

FIGURE 1.10 Ruler and caliper.

FIGURE 1.11 A varicocele is seen in the left hemiscrotum of an adolescent boy.

symmetry consistently during puberty. Assessing the testicular volume with either orchidometer can yield larger volumes than are obtained sonographically due to the inclusion of scrotal skin and epididymis, artifacts that can be overcome with experience with the orchidometers. In a study of 769 boys aged 6 months to 18 years, Goede and collaborators demonstrated an accurate correlation between volume measurements by ultrasound and by the Prader orchidometer, and concluded that "the Prader orchidometer can be used as a valid parameter for monitoring testicular growth."[46] Chipkevitch described a model to assess pubertal growth similar to the Tanner scale, in which he described various average testicular volumes for a given stage.[47] The "genital stages" correspond to similar stages in the Tanner scale. Based on a graphic model developed by Chipkevitch to assess testicular volumes, the expected testicular volume for the different pubertal stages is[48]

- *Stage I (G1)*: Volume less than 1–3 cc
- *Stage II (G2)*: Volume between 4 and 8 cc
- *Stage III (G3)*: Volume between 9 and 12 cc
- *Stage IV (G4)*: Volume between 13 and 16 cc
- *Stage V (G5)*: Volume greater than 16 cc

In a cross-sectional, population-based study, Tomova and coauthors evaluated a large population of patients for testicular volume (using a Prader orchidometer), penile size (length and circumference), body weight, and height.[49] This recent reference may serve as a contemporary range for the assessment of testicular volumes during puberty.

On physical exam, varicocele can be differentiated from noncommunicating hydrocele largely based on appearance. Varicocele is a dilation of the pampiniform plexus and internal spermatic vein due to incompetent internal spermatic vein valves. It is painless, is more common on the left side, and has a characteristic "bag of worms" appearance (Figure 1.11). Varicoceles may not be apparent unless the patient is standing up, and the examination of a pubertal and postpubertal male should always include evaluation of the scrotum while the patient is standing.[50] Noncommunicating hydrocele also presents as a nontender unilateral scrotal swelling but has a visibly smoother contour, and is not as susceptible to fluctuation due to positional changes, as it is a closed space and therefore more difficult for the fluid to escape.

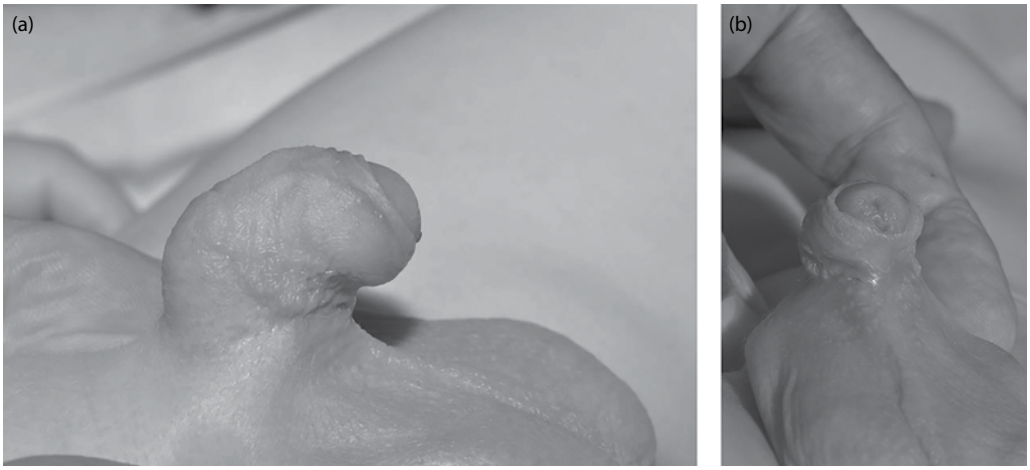

FIGURE 1.12 Chordee.

FIGURE 1.13 Ectopic hypospadic meatus.

FIGURE 1.14 Glanular (penile) adhesions.

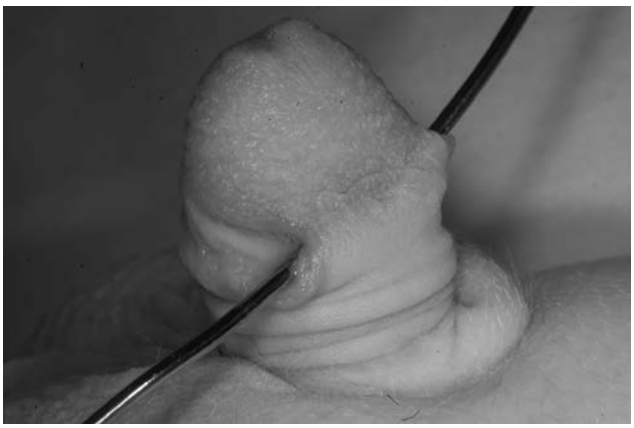

FIGURE 1.15 Dorsal skin bridge to the glans following newborn circumcision.

Examination of the Penis

In the male patient, the examination of the penis is conducted next. The child to this point should be comfortable with the exam, and the transition to the examination of the penis should be painless and well tolerated by the patient. The presence of a foreskin and appearance of the glans should be noted, as well as the presence of any penile abnormalities, including hypospadias, penile torsion, and chordee (Figure 1.12). Occasionally, the urethral meatus may be in an ectopic location in boys with hypospadias (Figure 1.13). In circumcised boys, the glans should be assessed for the presence of mucosal adhesions (Figure 1.14) or skin bridging (Figure 1.15). A hidden or congenitally buried penis (Figure 1.16a) should be differentiated from the rare but far more serious micropenis, which it might sometimes mimic (Figure 1.16b). When a micropenis is suspected, measurement of the stretched penile length with a ruler is necessary, while pressing the prepubic fat away. If the child remains cooperative, the various abnormalities identified during the exam should be demonstrated to the parents as part of their education

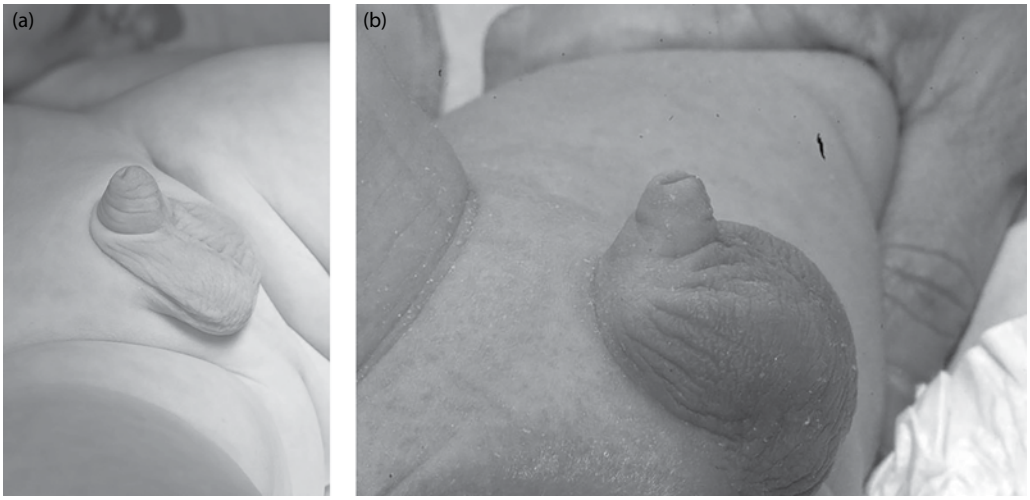

FIGURE 1.16 Hidden (concealed) penis (a), which mimics a micropenis (b).

into their child's urological condition. In the normally uncircumcised male, the foreskin should be retractile by 5 years of age, although some residual glanular preputial adhesions may remain at that age. Gentle, atraumatic retraction of the prepuce should be attempted. The prepuce should be assessed for the phimosis, and the presence of a pale, thick, annular scar suggests lichen sclerosus (Figure 1.17). Observation during urination, an important component of the physical examination, should be done to assess for possible ballooning during urination (Figure 1.18) in phimosis, or deflection of the urinary stream in meatal stenosis (Figures 1.19 and 1.20), while the boy pushes the penis down to direct the stream into the toilet bowl. The opportunity to assess a boy during urination invariably yields relevant information about the patient's condition, such as the caliber and orientation of the stream, presence of abdominal straining, interruption of the flow (staccato pattern) or intermittency, and postvoid dribbling. Some boys with "wetting" may be discovered to rush through voiding by barely lowering the waist of the pants to the penoscrotal junction, and then bending the penis over this obstacle, in essence entrapping the penis in an awkward position. Upon completion of urination and returning the penis to the normal anatomical position inside the underpants, the distended urethral bulb empties into the underpants, thus the wetting. The location and size of the meatus should be noted, remembering that a small meatus on examination is not always indicative of urethral meatal stenosis (Figure 1.20). The appearance of the deflected urinary stream during the assessment of the urinary flow in the toilet-trained patient will confirm if urethral meatal stenosis is present[51] (Figure 1.20).

FIGURE 1.17 Phimosis and annular cicatrix suggesting lichen sclerosus.

Examination of Penile Size and Micropenis

A micropenis is defined as a penis that is 2.5 standard deviations below the mean for a given age, without any hypospadic abnormalities. A micropenis is typically normally proportioned, with an appropriate ratio of shaft diameter to length (Figures 1.21 and 1.22). By this definition, the penis should measure at least 1.9 cm in a newborn, full-term infant to be considered normal.

The pediatric urologist is often consulted to evaluate a small penis in three rather distinct clinical scenarios. The first scenario is that of the newborn who does not undergo a neonatal circumcision because of the small-appearing penis. In this situation, it is critically important to differentiate a micropenis from a congenitally buried penis (Figure 1.23). A second scenario is that of the child who appears to have a small penis, which could represent a micropenis or a hidden penis secondary to prominent prepubic fat (Figures 1.24 and 1.25). The last scenario is that of the older prepubertal child whose somatic growth exceeds genital growth and the discordant growth creates concern about the size of the apparent "buried" and small penis (Figure 1.26). An inadequate or small-appearing penis may cause significant anxiety in both parents and the affected child. The topic must therefore be discussed with great care, whether or not the concern about penis size is well founded. The pediatric urologist should appropriately measure the length of the penis, even in cases where the diagnosis of micropenis appears unlikely, as a quantifiable discrepancy between the child's penile length and a length that would constitute micropenis may alleviate some of the concerns of the parents. In a child with below-average penile length, the

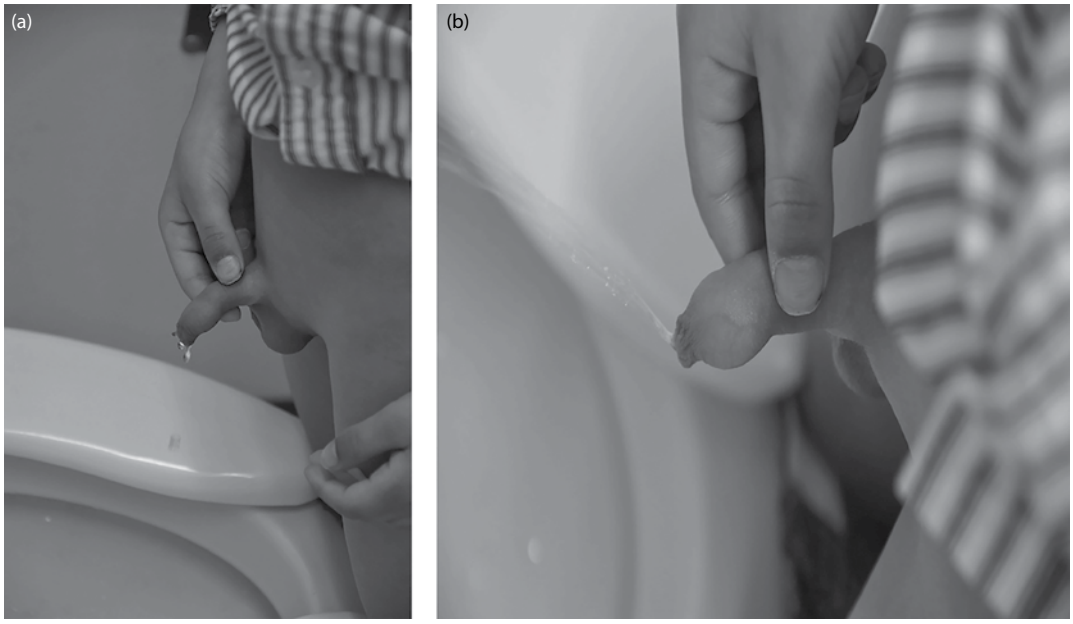

FIGURE 1.18 Ballooning of prepuce during urination.

physician should emphasize that the penis is of "normal size" rather than focus the conversation on what the mean length ought to be.

The standard method of measuring penile length is to lay the child in the supine position and place one end of a plastic ruler, flexible tape measure, or caliper on the pubic symphysis at the base of the penis (Figure 1.27). The examiner may then use his or her other hand to stretch the penis, measuring the distance between the pubis and the tip of the glans.[52] The reason the penis must be stretched is because stretched length, rather than relaxed penile length, more closely correlates with the length of the erect penis (Figure 1.27) (Video 1.1).

FIGURE 1.19 A boy with urethral meatal stenosis demonstrates the typical fine-caliber stream and the need to point the penis downward, toward the floor, in order to target the toilet.

An alternative, although less commonly used, method of measuring penile length in infants is with the aid of a modified syringe. In this technique, the needle end of a disposable 10 mL plastic syringe is cut and the piston is inserted into the cut end. The flanged end is then placed over the penis and pressed firmly into the pubis, creating a seal. The piston is then pulled back, drawing the penis into the barrel, partly erect. This excludes the supra pubic fat and allows the penile length to be noted on the scale printed on the syringe. Proponents of this method believe it to be less prone to individual variation than the standard method outlined above[53] (Figure 1.28).

Finally, penile length may be measured sonographically by using ultrasound to measure the length of the corpora.[54]

In obese children, the penis may appear smaller than its measured length due to a large suprapubic fat pad, which allows only a small portion of the penis to protrude beyond the abdominal wall. Likewise, patients with buried penis or webbed scrotum may be mistakenly diagnosed with micropenis. In buried penis, there is a deficiency of penile shaft skin and an abnormal attachment of the dartos fascia to Buck's fascia, causing entrapment of the penis in the subcutaneous tissue. In webbed scrotum, the scrotal sac attaches to the shaft of the penis at the ventral aspect of the shaft rather than the base of the penis, making the penis appear smaller[55] (Figure 1.29).

Common causes of micropenis include testosterone deficiency (or insensitivity) syndromes, abnormalities of the pituitary–hypothalamic axis, or cloacal exstrophy. Micropenis is also associated with chromosomal abnormalities, such as Down's syndrome, Klinefelter's syndrome, and Prader–Willi syndrome. Lastly, many cases

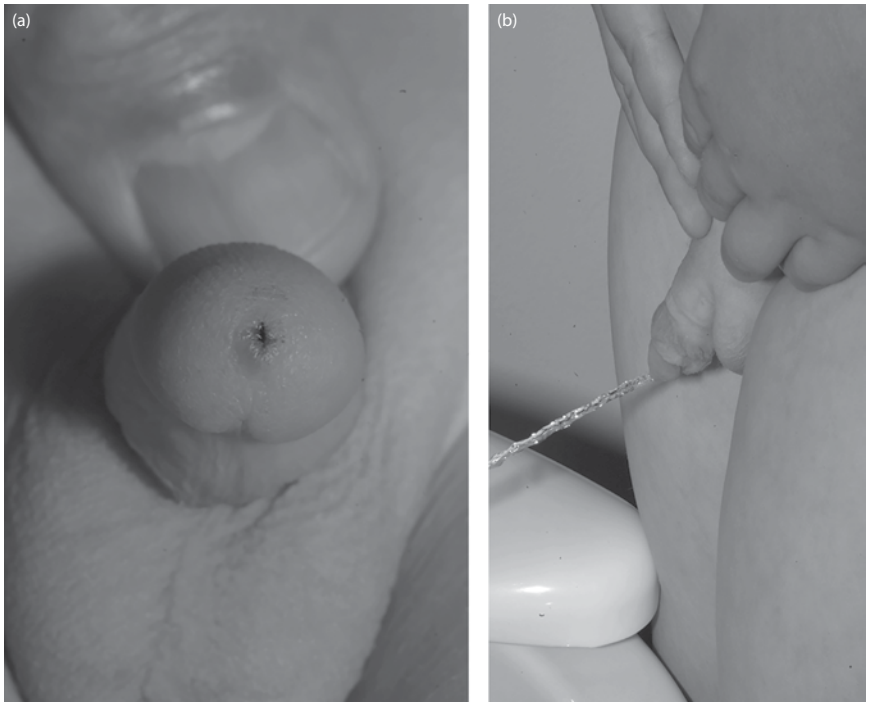

FIGURE 1.20 A boy with urethral meatal stenosis demonstrates the typical fine-caliber stream and the need to point the penis downward, toward the floor, in order to target the toilet.

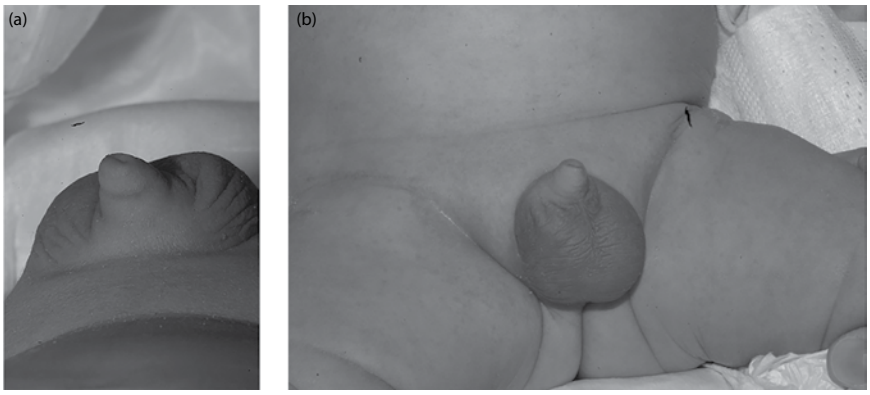

FIGURE 1.21 Micropenis.

FIGURE 1.22 An infant with congenital hidden penis demonstrates a penile length of *at least* 1.9 cm.

do not present with associated abnormalities, and are referred to as idiopathic micropenis. All these cases warrant a careful endocrinological evaluation.

Examination of the Vulva

The vulva consists of the external genital organs of the female. These include the mons pubis, labia majora, labia minora, clitoris, vulvar vestibule, urethral meatus, hymen, and genital glands (sebaceous, Skene's, and Bartholin's). During the physical examination, the vulva should be carefully inspected and any visible abnormalities palpated. Prior to beginning the examination, permission should be asked of the parents and the steps of the exam should be described. It is prudent to have a female nurse or other healthcare provider present as a chaperone during the exam. Examination of the genitalia in the preadolescent female is best conducted in the supine position with the legs in a frog-like position, with the soles of the feet touching each other. If this is not satisfactory, then a knee–chest position, asking the patient to perform Valsalva's maneuver, will allow satisfactory inspection of the introitus.[56] This should be the last part of the examination, and the girl may remain clothed until then. Practicing this part of the exam with a nurse prior to the physician conducting the genital exam may reduce the girl's apprehension related to the exam. To this effect, we often will tell the patient that a nurse is coming to help her undress and to teach her a task. Talking to the girl and explaining what we are doing in a friendly, but professional, manner is also helpful in comforting the patient. Depending on the age of the patient, the examination can be conducted while the girl remains in her mother's lap. If the child is placed on the exam table, the mother is encouraged to bend over to embrace the child and offer additional comfort. Distracting the child with a stethoscope or other toy and soliciting the help of the parents to comfort the child may go a long way in aiding relaxation. We ask the girl to try to touch the wall against the table with her knee, effectively encouraging her to flex and abduct her hips. After observing the external genital appearance, the labia majora are firmly, but not tightly, grasped between thumb and index finger, and pulled outwards and upwards, allowing full assessment of the open introitus, distal vaginal canal, and urethral meatus[57] (Figures 1.30 through 1.35). Any discharge or pooling of urine in the introitus should be further assessed with appropriate imaging studies. A pelvic examination, if necessary in the prepubertal female, should be conducted under general anesthesia, as manipulation and insertion of fingers or devices may have long-lasting psychologic consequences. Upon completion of the examination of the introitus, the girl is placed on her side to assess the appearance of the anus, as well as the cutaneous and bony aspects of the low back. Attention should be given to the presence of dimples, scoliosis, discolored skin patches, or hairy nevi in this area. The examination of the lower extremities completes the examination, and particular attention should be given to symmetry, strength, and skin temperature. The degree of estrogenization may be inferred by examining the female escutcheon. This is of particular importance when precocious or delayed puberty is suspected, and can be quantified by Tanner staging (see above).

The vulvar skin should be examined to look for changes such as erythema, edema, excoriations, ulceration, bullae, or rash. Such lesions may be due to a variety of causes, from trauma to sexually transmitted infection to contact dermatitis to chronic irritation due to urinary incontinence. A painful ulceration in an adolescent is most likely due to coalesced herpes simplex lesions or, less commonly, chancroid, while a painless ulcer is likely due to syphilis. Multiple flesh-colored papules and/or small

FIGURE 1.32 Infant vulva.

FIGURE 1.33 Introital exam of a child.

cauliflower-like lesions (condyloma accuminata) are the result of human papillomavirus (HPV) infection.

When there is a history of labial or inguinal swelling, the labia should be palpated to rule out hernia (Figure 1.36). The inguinal lymph nodes should also be examined, as palpable inguinal nodes signify infection or cancer.

In patients in whom sexual abuse is suspected, the hymen should be examined for tears or other signs of trauma. In patients with delayed menses and normal secondary sexual characteristics, imperforate hymen should be ruled out.

In sexually active patients, the edges of the introitus should be examined for evidence of vaginal discharge, which may be the result of bacterial vaginosis or sexually transmitted infection. Classically, the discharge from

FIGURE 1.34 Introital exam of an older girl.

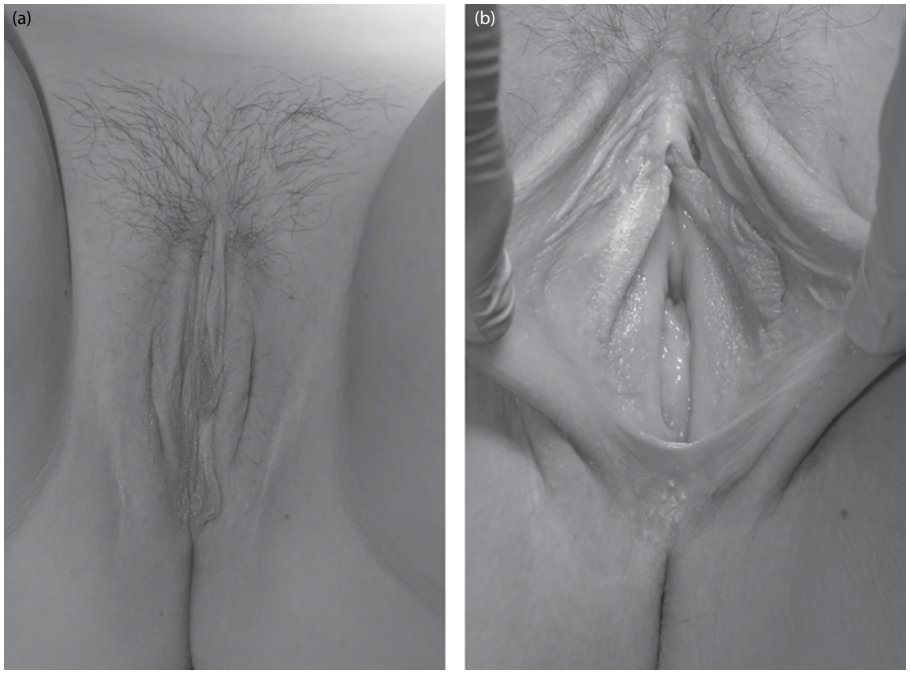

FIGURE 1.35 Female Tanner stage III.

chlamydia is described as mucopurulent, while the discharge from gonorrhea is purulent, although in reality they may be difficult to differentiate. The absence of discharge, however, does not rule out infection.

In patients complaining of dysuria, the urethral meatus should be examined for lesions, prolapse (Figure 1.37), and discharge. Discharge may be a sign of urethritis and should be sent for gram stain and culture.

The clitoris should be examined for signs of virilization. This is of particular importance in newborns, in whom a virilized clitoris may be a sign of inappropriate sexual development (disorder of sexual differentiation) (Figure 1.38). However, normal-appearing genitalia at birth do not guarantee normal sexual development. Patients with nonclassical (late-onset) 21-B-hydroxylase deficiency may present during later childhood or puberty with abnormal pubertal development and virilization.

In preadolescent girls, a speculum is usually not required. If there is an acute trauma or active vaginal bleeding, such an exam should be performed under anesthesia.

FIGURE 1.36 Bilateral inguinal hernias in a female.

FIGURE 1.37 Urethral prolapse.

FIGURE 1.38 Clitoromegaly.

This will allow for a thorough exam while minimizing trauma, both physical and psychological, to the patient.

Examination of the Anal Region

The anal region may be examined in a variety of positions, with supine being the most common in small children. As long as the entire anal area can be clearly visualized, the position that is most comfortable for the patient should be utilized.

Examination of the anal region is largely based on inspection. A rectal exam is rarely required. A digital rectal examination should be reserved for special circumstances, such as a patient with urinary retention, assessment of the neurologically impaired child, or in cases of severe constipation, and it is best performed using a well-lubricated, gloved, small fifth finger. If the digital rectal exam is necessary but not possible in the office setting, the examination should be conducted under anesthesia. In patients with spinal cord injury, the bulbospongiosus reflex should be assessed by squeezing the glans or clitoris and sensing for an anal sphincteric contraction.

The anal region (as well as the perineum) should be carefully inspected in any child with fecal or urinary incontinence.

In patients complaining of pain in the anal region, a broad differential diagnosis may be easily narrowed by physical exam. For example, children who have pain in the anal region due to chronic constipation may have anal tears or fissures on exam from the passage of hard stools. Examination of a child who refuses to sit on his or her buttocks may reveal a pilonidal cyst or hemorrhoids. Acute onset of anal pain in a young child while unsupervised may reveal a foreign body or trauma. In cases of anal trauma, sexual abuse should be considered, particularly if the history is unclear.

Examination of the Back

For the pediatric urologist, examination of the back consists of two distinct components: evaluation of the kidneys and evaluation of the spine. Evaluation of the kidneys should begin with evaluation of the patient's posture. Abnormalities of the spine are significant because they are associated with tethered cord, spina bifida, and other spinal cord lesions, which can profoundly affect bladder function. Examination of the spine should always begin with evaluation of spinal curvature. This is best done by examining the patient's bare back with the patient first in the seated and then in the standing position. Abnormal curvature of the spine is possible in the frontal plane (scoliosis), as well as the sagittal plane (kyphosis or lordosis). The more significant the curvature, the more likely it is that the patient will possess neurologic deficits.

Examination of the patient's back for signs of abnormal spinal development should be carried out in all newborn infants and children with bladder dysfunction. These signs can range from subtle to profound. Subtle signs of spinal defects include a sacral dimple, patch of hair, hemangioma (Figure 1.39), lipoma, aberrant gluteal cleft, or decreased tone of the anal sphincter. If any of these signs are present, further imaging should be pursued. Conversely, some open spinal cord defects, such as myelomeningocele, may be grossly visible and should be referred for neurosurgical intervention as soon as possible.

Examination of the Extremities

Examination of the extremities is less pressing than other aspects of the physical exam. Still, the extremities provide useful information that can aid in the diagnosis of various urological conditions.

Most obviously, the extremities are useful for the examination of vital signs. A discrepancy in the strength of the pulse bilaterally or between the upper and lower body may point to coarctation of the aorta. Hemangiomas on the skin of the extremities may disclose arteriovenous malformations

FIGURE 1.39 Sacral hemangioma.

that can affect the renal arteries. Unexplained paralysis or parasthesias of the extremities may aid in localizing a spinal cord lesion that may concomitantly affect bladder function. The finding of club feet should prompt further neurosurgical and orthopedic evaluation. The finding of extremity asymmetry or hemihypertrophy should prompt sonographic evaluation of the kidneys for association with Wilms' tumors. Finally, congenital limb defects, particularly of the radius, may be a manifestation of VACTERL association.

Neurological Exam for the Pediatric Urologist

An uncomplicated neurologic examination can be easily performed in most children, and in the context of the urologic patient, this part of the examination is usually reserved for patients with voiding disorders. Normal-appearing patients with genital disorders will rarely have neurologic conditions that can be uncovered by the urologist, and neurologic examination of the infant and young child by the urologist is usually unnecessary. In the older child and adolescent, the neurologic exam should include assessment of mental status, muscle tone and strength, reflexes, cerebellar function, and sensory responses.

Muscle tone is the degree of resistance of a patient's muscles to passive motion. A patient's muscle tone may be normal, hypertonic, or hypotonic. Hypertonia is generally the result of an upper motor neuron lesion, while hypotonia generally results from lower neuron lesions. The two most common types of hypertonia include spasticity, where the resistance of a muscle increases progressively as the muscle is stretched, often followed by a "clasped knife" phenomenon in which there is a sudden release of tone following the point of maximal tone, and rigidity, where there is resistance through the full range of motion of a muscle. Particularly pertinent to the urological exam is the tone of the anal sphincter, which may be appreciated by digital rectal exam. Abnormal tone of the anal sphincter suggests similar changes in the urinary sphincter and may be the result of neurogenic disease.

Muscle strength is the ability of the patient to generate the contraction against resistance. It is characteristically measured on a scale of 0–5. A score of 0/5 indicates no contraction, such as in a completely paralyzed muscle group. A score of 1/5 indicates muscle twitching or slight contraction but no visible movement of the joint itself. A score of 2/5 indicates movement while not working against gravity (i.e., the axis of movement is perpendicular to the gravitational plane). A score of 3/5 indicates the capacity for movement against gravity but not against the examiner's resistance. A score of 4/5 indicates movement against some degree of examiner resistance, although the degree of resistance is less than expected. A score of 5/5 is normal strength against resistance.

Reflexes are involuntary muscle contractions elicited by muscle stretch (deep tendon reflexes) or superficial stimulation (cutaneous reflexes). Reflexes provide information about the integrity of spinal nerves at a given spinal cord level. They are graded on a scale of 0–4: 0/4 is areflexia, 1/4 is weaker than expected, 2/4 is normal, 3/4 is hyperreflexia, and 4/4 is significant hyperreflexia with clonus. In general, hyporeflexia is the result of lower motor neuron disease, while hyperreflexia results from upper motor neuron disease. The most commonly tested deep tendon reflexes include the patellar (L2-L4), Achilles (S1), biceps (C5-C6), and triceps (C7-C8) reflexes. Maneuvers that redirect the patient's attention (Jendrassik maneuver, having the patient look away while performing the exam) make reflexes easier to elicit, as they promote relaxation and prevent anticipatory suppression.

Commonly tested cutaneous reflexes include the cremasteric reflex, bulbocavernosus reflex, and anal wink reflex. The cremasteric reflex may be elicited by lightly stroking the superior-medial aspect of the patient's thigh. The expected response is an immediate contraction of the cremasteric muscle with consequent elevation of the ipsilateral testicle.

The bulbospongiosus (bulbocavernosus) reflex is an indicator of spinal cord injury involving the S2-S4 spinal nerve roots. It may also be absent in spinal shock, and is one of the first reflexes to return once spinal shock has dissipated. The bulbospongiosus reflex may be elicited by squeezing the glans penis (or tugging on a Foley catheter). The reflex response should be a contraction of the anal sphincter.

The anal wink reflex is similar to the bulbocavernosus reflex and also tests the integrity of the S2-S4 nerve roots. To elicit the anal wink reflex, the perianal skin is stroked with a sharp object (i.e., safety pin) to stimulate the cutaneous nociceptors. The result is contraction of the anal sphincter.

The cerebellum is largely responsible for the coordination of muscle movements; thus, disorders of the cerebellum result in disorders of coordination. Gross disorders of the cerebellum may be picked up by general observation and do not require special exam maneuvers. The patient may present with gross ataxia, nystagmus, or dysarthria. Patients with more subtle findings (and who are old enough to follow directions) may be more closely examined. The patient may, for example, be asked to keep a rhythm by tapping on the table, or may be asked to perform rapidly alternating movements, such as fast alternating pronation and supination of the hand. Other commonly used tests to check for cerebellar dysfunction include heel-to-shin (asking the patient to continuously rub the plantar aspect of their foot up and down the shin of their opposite leg in a smooth manner) and finger-to-finger (asking the patient to use their index finger to quickly alternate between touching their nose and then the examiner's index finger) tests.

The final component of the neurological exam is the sensory exam. In the urological patient, this is typically limited to examination of sensation in specific dermatomes (area of skin with sensation supplied by fibers from a single dorsal root). The most important dermatomes include the top of the foot (L5), bottom of the foot (S1), and perineum (S2-S4).[58,59]

DOCUMENTING THE PATIENT ENCOUNTER

The gathering of medical information occurs in many scenarios in the field of pediatric urology. The interaction with an expectant mother with a prenatally detected urologic malformation is very different from the interaction with an acutely ill boy with scrotal pain. Just as the types of questions and data gathering need to be adjusted according to a given medical scenario, so does the documentation of that

encounter. In the 1990s, the "Documentation Guidelines for Evaluation and Management Services" were developed by the Health Care Financing Administration (HCFA) and the American Medical Association, and since then, many variations of these guidelines have evolved. The guidelines, commonly referred to as the Evaluation and Management (E/M) services guidelines, were developed with the premise that medical interactions should provide specific documentation of the history, physical examination, and decision-making process, in order to be processed and reimbursed by Medicare. Each interaction, be it with a new or an established patient, is coded according to the number of items (bullets) covered during the interaction. Three broad categories are used (office visits, hospital visits, and consultations), and each of these categories is further subdivided according to a new or established interaction with a patient.[60–62] In the context of this chapter, it is necessary to mention this newer component of the medical history and physical examination, although it is not the intent of this chapter to expand on these complex and controversial coding guidelines.

CHAPTER
2

Laboratory Assessment of the Pediatric Urologic Patient

Paul F. Austin and Elizabeth B. Roth

INTRODUCTION

In general, laboratory assessment of the pediatric urologic patient is not as extensive as in the adult counterpart. Patients tend to be healthier, and there are no recommended routine preoperative laboratory screening tests for pediatric urologic patients. However, there are certain instances when laboratory examination in pediatric urology is invaluable. This chapter outlines the most common laboratory tests used in pediatric urology, demonstrating the clinical scenarios in which each test should be employed.

COMMONLY ORDERED LABORATORY EXAMINATIONS

Urinalysis and Urine Culture and Sensitivity

The most commonly utilized laboratory examinations in pediatric urology are urinalysis with urine microscopy and urine culture and sensitivity. These urine tests are routinely ordered to identify a potential infection prior to invasive urologic procedures. A urinalysis with urine culture is also standard of care in investigating a fever of unknown origin in the infant. The prevalence of urinary tract infection (UTI) in pediatric patients with fever of unknown origin is 5%.[1] If a UTI is identified, the child requires more extensive testing to rule out further urologic pathology or anatomic abnormalities.

When children present with symptoms suggestive of a UTI, such as dysuria, genital pain, diurnal enuresis, urgency, frequency, and urinary retention, it is important to understand that they may not have a UTI. These children may have a history of incomplete bladder emptying or a history of bladder and bowel holding termed "dysfunctional elimination."[2] A urinalysis and urine culture can help to discriminate between UTIs and the irritative voiding symptoms inherent to this group.[1] Dysfunctional eliminators may have irritative voiding symptoms secondary to their behavior, but they also have a higher risk of UTIs. When a UTI is identified, antibiotic treatment is essential acutely, but behavioral modification is the mainstay of treatment for children with dysfunctional elimination.[2,3]

It should be noted that there are certain instances in which the urinalysis should be interpreted with caution. In patients who perform clean intermittent catheterization, or who have undergone bladder reconstruction using intestinal segments, testing should be selective, as a positive urinalysis in these patients may only represent colonization with bacteria (see Figure 2.1). Antimicrobials are used when symptoms of infection, such as dysuria, pelvic pressure, and fever, accompany a positive urinalysis and urine culture. Overtreatment, however, may lead to the development of highly resistant organisms.[4–6]

Additionally, the method of collection can impact interpretation of laboratory urine tests. For example, a pediatric "clean catch" urine specimen may yield growth not necessarily representative of an infectious process. In our practice, we are careful to interpret urine collected from bagged specimens. Although a bagged specimen is a useful, noninvasive method for collecting urine from a non-toilet-trained child, this method can easily have a false-positive growth secondary to contamination from bacteria colonized on the genital and perineal skin. It is helpful when the bagged specimen results are negative, or if there is a single isolate on the culture. It is also important to obtain both urinalysis and culture, as the absence of leukocytes in a specimen with positive culture should make one suspect contamination. If it is unclear whether there is truly infection, the urine specimen may need recollection via catheterization.

Serum Blood Urea Nitrogen and Creatinine

Serum blood urea nitrogen (BUN) and creatinine are frequently obtained as measures of renal function. When interpreting these tests, the clinician must be aware of the impact of the size of the child, as well as their age. For example, the neonate's renal function is a reflection of maternal renal function at birth, and the creatinine levels remain similar to the maternal serum creatinine for the first several days of life prior to decreasing to normal infant levels. Premature neonates in particular will have higher levels of creatinine and take longer to approach infant levels than full-term neonates.

Serum BUN and creatinine yield insight into renal function both as a baseline marker and as a method of longitudinal monitoring. With the diagnosis of prenatal and

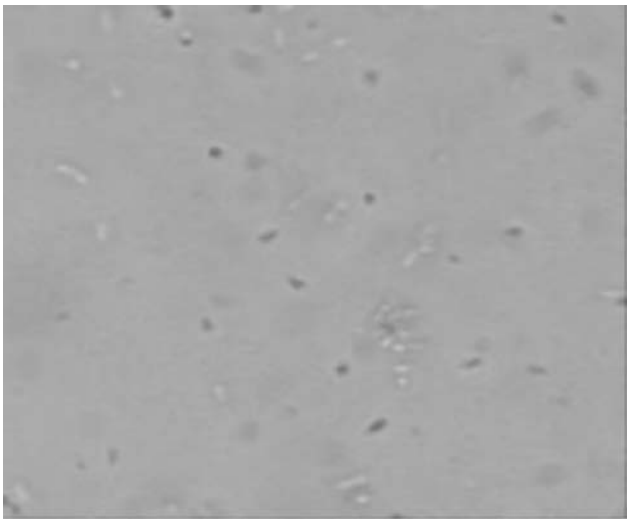

FIGURE 2.1 Asymptomatic bacteriuria. In patients on intermittent catheterization or with intestinal augmentation or diversion of the bladder, bacteria are often observed on urine microscopy. Note that there are no red blood cells (RBCs) or white blood cells visible on microscopy to indicate infection in this specimen.

perinatal abnormalities, such as oligohydramnios (potentially secondary to bilateral renal agenesis, bilateral ureteropelvic junction (UPJ) obstruction, bilateral multicystic dysplastic kidney, or posterior urethral valves) or hydronephrosis (due to UPJ obstruction, congenital megaureter, posterior urethral valves, or vesicoureteral reflux), serum BUN and creatinine are important parameters that help determine the overall prognosis, as well as in monitoring therapeutic effectiveness. For example, a serum creatinine of more than 1.0 mg/dL at 1 year of age in a child with a history of posterior urethral valves is associated with poor renal outcome.[7] Other high-risk patients that require close monitoring of serum creatinine include patients with renal scarring that can be associated with vesicoureteral reflux[8] or with a neurogenic bladder.[9]

Complete Blood Cell Count and Coagulation Studies

A complete blood cell count (CBC) and coagulation studies are not routinely obtained prior to most pediatric urology interventions. This is primarily due to the outpatient nature of pediatric urology procedures that are associated with low morbidity. There are certain patient populations, however, for whom these hematologic laboratory tests are indicated. These include children with chronic anemia, a family history of hematologic disorders, or coagulopathic tendencies.

Important preoperative hematologics tests consist of a CBC, prothrombin time (PT), international normalized ratio (INR), and partial thromboplastin time (PTT). A lower-than-average hematocrit can be seen in children with sickle cell anemia and does not necessarily require intervention. If a value represents a significant change from baseline, or if the patient is symptomatic or unstable, then hematologic intervention is recommended. Patients with platelet disorders, such as von Willebrand disease, may have an adequate number of platelets on CBC, although these platelets function poorly. In these patients, additional testing may be required, including obtaining serum levels of von Willebrand factor (vWF) VIII, vWF ristocetin cofactor activity (vWFRCo), and bleeding time (BT), in addition to CBC, PT, and PTT. Oncology patients are often pancytopenic, and procedures should be coordinated with chemotherapy cycles and administration of colony-stimulating factors, in order to maximize preoperative blood counts and minimize the chances for bleeding and infection.

Multiple clinical practice guidelines for perioperative transfusion exist for both adult and pediatric patients.[10–12] With respect to surgery, or invasive procedures, all these guidelines state the following: In the absence of associated coagulation abnormalities, a platelet count of 40,000/μL to 50,000/μL is sufficient to perform most major invasive procedures with safety. For minor procedures, a lower threshold of 10,000/μL to 20,000/μL can be used.[10–12] If platelet transfusions are administered before a procedure, it is critical that a posttransfusion platelet count be obtained to prove that the desired platelet count has been reached. Platelets should also be available on short notice in case intraoperative or postoperative bleeding occurs. In summary, hematologic values must be considered within the context of careful clinical evaluation of each individual patient, as well as the morbidity of the surgical procedure. Good communication with the pediatric hematologist will help steer the appropriate laboratory testing.

COMMON PEDIATRIC UROLOGIC CLINICAL SCENARIOS AND REQUISITE LABORATORY TESTS

Hematuria

When a child presents with hematuria, a number of tests are potentially indicated. Depending on the degree of hematuria, and whether it is gross or microscopic, there are many potential etiologies (Table 2.1). Most hematuria originates in the renal parenchyma and is termed nephrologic hematuria. It is incumbent on the urologist to distinguish nephrologic bleeding from that caused by surgically significant sources.

Hematuria is often first noticed on a urine dipstick performed at the primary care office. A microscopic analysis of the urine should follow a positive dipstick. A freshly voided urine specimen should be used for this purpose. An approximately 10–15 mL aliquot of the urine is spun in a centrifuge at 1500 rpm for about 5 minutes. The supernatant is decanted and the sediment is resuspended in the remaining liquid and placed on a glass slide with a coverslip. Careful examination of the urine sample is then conducted under high-power magnification. All noncellular and cellular elements seen should be noted and recorded. The presence of more than five red blood cells (RBCs) per high-powered field generally is considered abnormal. The detection of RBC casts is indicative of a glomerulotubular source of hematuria (Figure 2.2). The absence of RBCs and RBC casts despite a positive dipstick test is suggestive of hemoglobinuria or myoglobinuria. This is important because a positive urine dipstick for

TABLE 2.1 Differential diagnosis of hematuria in the pediatric population

Glomerular Origin

- IgA nephropathy
- Alport's syndrome
- Benign familial hematuria
- Membranoproliferative glomerulonephritis
- Acute poststreptococcal glomerulonephritis
- Rapidly progressive glomerulonephritis
- Systemic lupus erythematosus
- Membranous nephropathy
- Henoch–Schönlein purpura
- Goodpasture's disease
- Focal segmental glomerulosclerosis

Interstitial and Tubular Origin

- Acute interstitial nephritis
- Acute pyelonephritis
- Tuberculosis
- Hematologic disorders
  - Sickle cell disease, von Willebrand disease, renal vein thrombosis, thrombocytopenia

Urinary Tract Origin

- Infection
  - Bacterial or viral, such as adenovirus
- Nephrolithiasis
- Structural/congenital anomalies
  - UPJ obstruction, hydronephrosis, vascular malformation, polycystic kidney disease
- Trauma
- Tumors
  - Renal cell carcinoma, Wilms' tumor, transitional cell carcinoma
- Exercise
- Medications
  - Aminoglycosides, amitriptyline, anticonvulsants, aspirin, chlorpromazine, coumadin, cyclophosphamide, diuretics, penicillin, thorazine

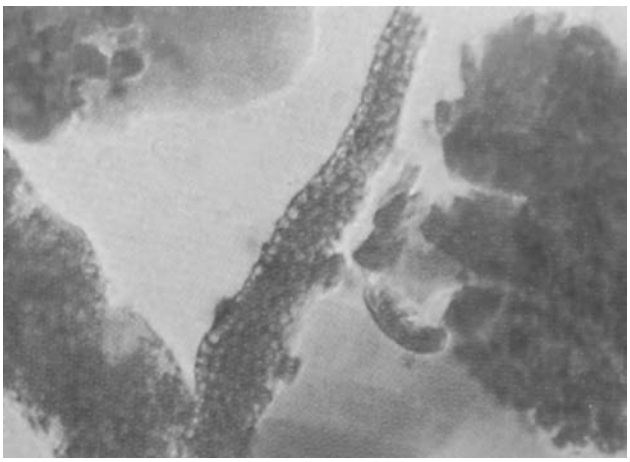

FIGURE 2.2 RBC casts. The RBCs are easily identified as biconcave discs embedded in the cast matrix. RBC casts are pathologic, and their presence is usually indicative of severe injury to the glomerulus. Occasionally, RBC casts may be seen in an individual who has been playing contact sports. The urine will usually return to normal within 24–48 hours.

RBCs may have a completely negative microscopic examination, and thus represent a false positive. Microscopic abnormal-shaped RBCs or dysmorphic RBCs are more commonly associated with nephrologic causes of hematuria, and normal-shaped or eumorphics RBCs are more commonly associated with urologic causes. The presence of proteinuria with dysmorphic RBCs further strengthens a nephrologic origin of the hematuria.[13]

Another practical test for microscopic hematuria in the outpatient clinic is a "spot" urine calcium/creatinine ratio.[14,15] If this ratio is >0.21 on two or three separate urine samples, this indicates hypercalciuria, although ratios can be significantly higher in infants.[16] Hypercalciuria does not necessarily result in nephrolithiasis but is a reported risk factor.[17] While most children with hypercalciuria do not progress to clinical nephrolithiasis,[18,19] recent reports suggest that persistent hypercalciuria may be associated with long-term bone demineralization and bone loss.[20]

It is important to note that the laboratory tests ordered for the evaluation of hematuria must be based on the clinical history and the physical examination. The physician should avoid automatically requesting tests that may be unnecessary. A panel of serum tests are selectively performed if renal and bladder sonography are negative and the urine microscopy suggests a nephrologic origin. These include CBC, basic metabolic panel, serum complement levels, antistreptolysin O (ASO) titer, and antinuclear antigen (Table 2.2). These may subsequently indicate hematologic or immunologic mediated diseases affecting the kidney.

Adrenal Mass

With the increased availability and usage of imaging modalities such as computed tomography (CT) and ultrasound, the incidence of incidentally discovered adrenal masses is increasing, in both adults and children.[21] While the vast majority of these lesions are benign and nonfunctioning lipomas or adenomas, it is incumbent upon the treating urologist to rule out a biologically active lesion through careful history and directed laboratory analysis. Unlike the adult population, the vast majority of incidentally discovered adrenal lesions are found in children already known to have medical adrenal disease, most commonly congenital adrenal hyperplasia (CAH).[22] Therefore, a newly discovered adrenal lesion should prompt a more thorough clinical investigation for risk factors for adrenal disease, including history of hypospadias or ambiguous genitalia, as well as a detailed family history of any relations with adrenal or renal lesions.

In lesions larger than 1 cm, a basic laboratory screening for biologically active lesions is indicated. Generally, this includes serum electrolytes, measurement of cortisol levels, and screening for pheochromocytoma. Screening for

TABLE 2.2 Serum panel for nephrologic hematuria

- CBC
- Basic metabolic panel
- C3 complement level
- Antistreptolysin O (ASO) titer
- Antinuclear antibodies (ANAs)

sex hormone secretion is not recommended in the absence of clinical signs of androgen or estrogen excess. Cortisol levels can be measured by a 24-hour urine free cortisol test, a late-night salivary cortisol measurement, or a low-dose dexamethasone suppression test.[21] In patients weighing greater than 40 kg, a 1 mg dose of dexamethasone is given at 11:00 p.m. and the serum cortisol measured the following morning between 8:00 and 9:00 a.m. In patients weighing less than 40 kg, the dose is adjusted to 30 μg/kg.[23] Screening for pheochromocytoma can be performed using either plasma or urinary metanephrines.[21]

Patients with abnormal screening results require further confirmatory testing prior to the diagnosis of a functioning adrenal lesion. In patients with hypertension or low serum potassium levels, the ratio of plasma aldosterone to renin should be measured. A ratio of greater than 20 with an overall aldosterone concentration of at least 15 ng/mL is diagnostic of an aldosterone-secreting lesion. Similarly, abnormalities of two of the three available screening tests for cortisol secretion are considered sufficient for diagnosis of a cortisol-secreting lesion. Either plasma or urinary metanephrines above the reference range are considered diagnostic for pheochromocytoma, but confirmatory testing is generally recommended. Biologically active lesions should generally be considered for surgical intervention.[21]

Testicular Mass

A child presenting with a testicular mass should have testicular tumor markers obtained. These include alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG), lactate dehydrogenase (LDH), and placental alkaline phosphatase (PLAP). These can be checked in the outpatient office setting or may be obtained in the operating room during the placement of the intravenous lines. These levels are important for staging, as well as monitoring progress during treatment.

A serum AFP level will be elevated in tumors containing yolk sac elements, which are the most common malignant germ cell tumor in prepubertal children, and commonly seen in nonseminomatous germ cell tumor in postopubertal males. It will not be present in histologically pure choriocarcinoma or seminoma. Of note, AFP at birth is relatively high and will remain so for the first several months of life, due to the yolk sac elements present during gestation (Table 2.3).[24] Additionally, AFP can be produced by the liver, pancreas, stomach, and lung; consequently, it may be elevated in diseases of these organs. In addition to ascertaining levels of tumor markers for testicular tumors, it is helpful to check liver function tests, as an elevation in these could indicate metastatic disease to the liver, which may or may not be visible on imaging.

TABLE 2.3 Average normal serum alpha-fetoprotein of infants

Age	Mean ± SD (ng/mL)
Premature	134,734 ± 41,444
Newborn	48,406 ± 34,718
Newborn–2 weeks	33,113 ± 32,503
Newborn–1 month	9,452 ± 12,610
2 weeks–1 month	2,654 ± 3,080
2 months	323 ± 278
3 months	88 ± 87
4 months	74 ± 56
5 months	46.5 ± 19
6 months	12.5 ± 9.8
7 months	9.7 ± 7.1
8 months	8.5 ± 5.5

Nephrolithiasis

The prevalence of nephrolithiasis in children is much smaller than in the adult population,[25] and extensive laboratory assessment is recommended upon initial presentation. As opposed to the adult patient, nephrolithiasis in the pediatric population is more likely attributable to a metabolic abnormality. In the office, a urine dipstick can be performed to measure the urine specific gravity and pH. Microscopic examination of the spun urine can be performed to assess for RBCs and urinary crystals.[26,27] Calcium oxalate dihydrate crystals are seen as colorless squares with intersecting lines (resembling an envelope) (Figure 2.3). Calcium oxalate monohydrate crystals vary in size and may have a spindle, oval, or dumbbell shape. Most commonly, they appear as flat, elongated, six-sided "fence picket" crystals. Triple-phosphate (struvite and magnesium ammonium phosphate) crystals usually appear as colorless, prism-like "coffin lids" (Figure 2.4). Uric acid crystals may appear as yellow to brown rhombic plates, needles, or rosettes, and cystine crystals have a characteristic hexagonal appearance (Figure 2.5).

Standard metabolic evaluation for pediatric nephrolithiasis includes serum tests and a 24-hour urine study (Table 2.4). A serum CBC, electrolytes, bicarbonate, calcium, phosphorus, BUN, creatinine, alkaline phosphatase, magnesium, and uric acid should be obtained.

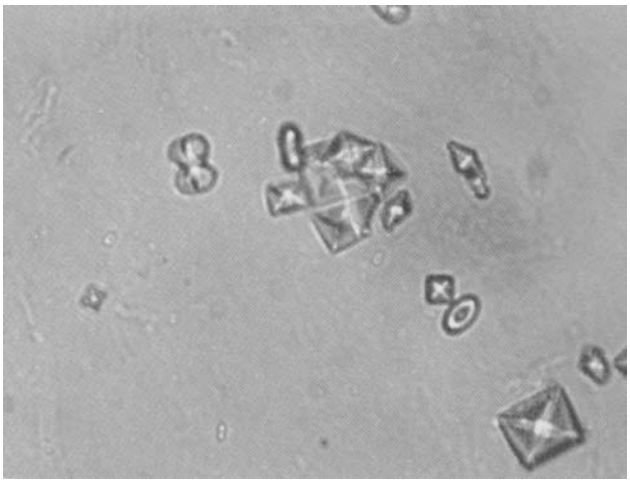

FIGURE 2.3 Calcium oxalate crystals. Calcium oxalate crystals most frequently have an "envelope" shape and appear in acid, neutral, or slightly alkaline urine.

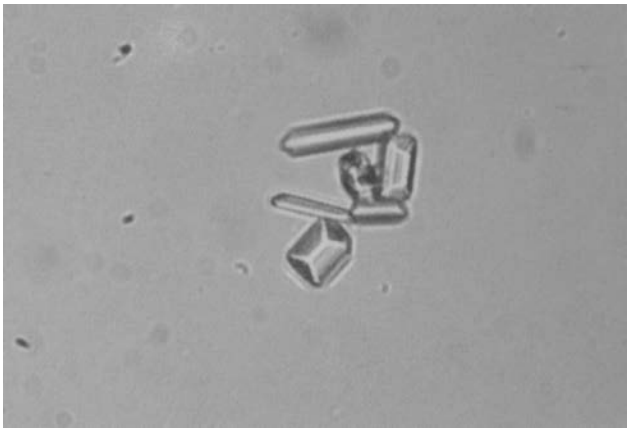

FIGURE 2.4 Triple-phosphate crystals. These crystals are common in urine sediment. Triple-phosphate crystals have a "coffin-lid" shape, are colorless, and appear in alkaline urine. These crystals may be found with struvite or magnesium ammonium phosphate stones.

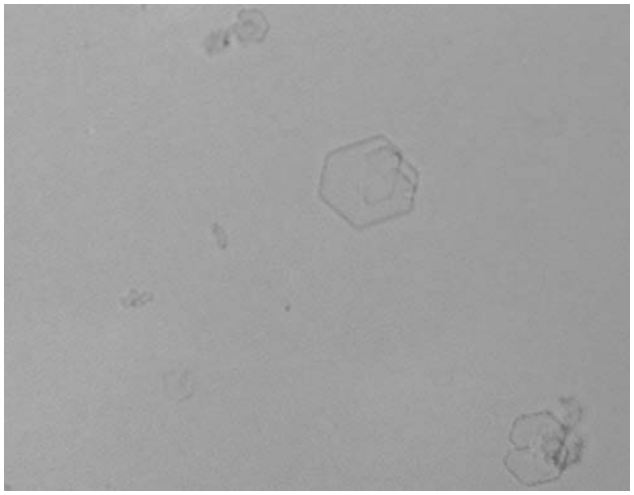

FIGURE 2.5 Cystine crystals. Cystine crystals are thin, hexagonal-shaped (six-sided) structures and appear in the urine of children with cystinuria.

TABLE 2.4 Metabolic evaluation of pediatric nephrolithiasis

Serum	Urine—24 Hour
• CBC • Basic metabolic panel • Uric acid • Calcium • Magnesium • Phosphorus • Alkaline phosphatase	• Volume • Calcium • Oxalate • Citrate • Phosphorus • Magnesium • Sodium • Uric acid • Cysteine

Elevated serum calcium suggests the possibility of hyperparathyroidism, and a serum intact parathyroid hormone level should be checked. A 24-hour urine collection should be obtained on a regular diet, to check calcium, phosphorus, magnesium, oxalate, sodium, uric acid, citrate, cysteine, creatinine, and volume.[25] The most common abnormalities seen on the 24-hour urine collection are diminished urinary volume indicative of poor hydration, hypocitraturia, and hypercalciuria.[28–31]

Intersex

The first laboratory tests ordered after a careful history and physical examination should be electrolyte assessment, a karyotype, and serum 17-hydroxyprogesterone (17-OH progesterone) levels. Obtaining electrolytes is important to identify any metabolic imbalances, such as the "salt wasting" seen in CAH that would require prompt intervention. Serum 17-OH progesterone is obtained early because elevated levels identify CAH, which is the most common intersex condition. Formerly, the child's karyotype was obtained by a buccal smear, but now it is obtained by chromosome analysis of peripheral blood lymphocytes. A fluorescent in situ hybridization (FISH) analysis may be done in conjunction with the chromosome analysis for rapid evaluation of sex chromosome presence. Although the FISH results will yield a karyotype within 24 hours, these results need verification from the formal chromosome analysis, which takes 2–3 days. Further testing will then be directed accordingly.[32,33] (See Chapter 72.)

Cryptorchidism

Nonpalpable testis in association with hypospadias requires an intersex workup. Unilateral nonpalpable testis in the presence of normal external genitalia does not require additional laboratory investigation, although a newborn with bilateral nonpalpable testes and normal male genitalia must be evaluated for female pseudohermaphroditism due to CAH. Determination of the presence or absence of the unilateral undescended testicle is accomplished via surgical exploration or diagnostic laparoscopy. In the case of bilateral, nonpalpable undescended testes in an older child, further laboratory assessment can be done to ascertain the presence of testicular tissue.

A karyotype should be performed as well as measurement of serum testosterone in cases of bilateral, nonpalpable cryptorchidism. Additionally, the serum gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) can be measured, and if these are elevated in the face of low testosterone, this is suggestive of anorchia.[34] It is important to note that serum testosterone is normally elevated during infancy in the neonate, at 2–3 months of age, as well as at puberty. Subsequently, serum testosterone can be measured in the neonate or during this natural surge of infancy. If this window of opportunity is missed or if evaluation is being done in the newborn period, then either an HCG stimulation test may be obtained or a measurement of serum Müllerian inhibiting substance (MIS).

Serum MIS levels produced by the Sertoli cell are the most sensitive indicator of testicular presence,[35–37] but unfortunately, the enzyme-linked immunosorbent assays (ELISAs) are not readily available in many centers. Subsequently, an HCG stimulation test is more frequently obtained. Several methods of HCG stimulation have been described.[38,39] One method is to administer HCG

intramuscularly (100 IU/kg or 5000 IU/1.7 m^2) one time and measure serum testosterone and dihydrotestosterone 72 and 96 hours later.[38] Another method involves three intramuscular injections of HCG on successive days at a daily dose dependent on their age (≤1 year old, 500 units; 1–10 years, 1000 units; ≥10 years, 1500 units).[39] The HCG should stimulate testicular Leydig cells, if present, to produce testosterone, resulting in a level of >200 ng/dL. If there is an appropriate increase in testosterone, then some functioning testicular tissue is present. If there is no response to HCG, then presumably the child is anorchid. However, there also exists the possibility of Leydig cell dysfunction, in that the Leydig cells do not respond appropriately to HCG. For this reason, many pediatric urologists still perform exploratory surgery, regardless of laboratory results.

Nocturnal Enuresis

Screening tests for nocturnal enuresis are necessary to rule out any organic etiology.[40] These include a urinalysis or urine dipstick to assess the urine specific gravity and the presence of glucose. If the specific gravity on the urinalysis is low, correlating to dilute urine, it suggests the possibility of diabetes insipidus (DI). If the urinalysis or urine dipstick demonstrates large amounts of glucose, this suggests diabetes mellitus may be present. Subsequent workup and testing can then be tailored accordingly.

CHAPTER 3

Fetal Urology and Prenatal Diagnosis

Joao Luiz Pippi Salle and Rodrigo L. P. Romao

INTRODUCTION

Since the introduction of antenatal ultrasonography in the 1970s, the number of pregnancies with a diagnosis of a urological malformation has systematically increased. Currently, the vast majority of pregnant women worldwide will undergo at least one prenatal ultrasonography (US) scan. Despite the existing evidence that an early prenatal US improves detection of multiple pregnancies and gestation dating, antenatal detection of congenital anomalies has not translated into improved perinatal mortality and major morbidity rates.[1] Nevertheless, the high sensitivity of urological anomaly detection (around 90%) has impacted significantly the practice of pediatric urology as a specialty.[2] The scope of practice has shifted from a primarily interventional/surgical model directed at symptomatic patients to a counseling role for those who are often asymptomatic and with problems of variable clinical significance.[3,4]

Antenatal hydronephrosis is seen in 1%–5% of all pregnancies and represents the most frequent prenatal diagnosis overall, with the majority of patients depicting mild, non-specific dilation of the renal pelvis that will resolve spontaneously.[3,5] Detection of this "abnormality" in the fetus is a source of parental anxiety and triggers requests for specialized consultation. Many of these babies have no significant urological pathology and become known colloquially as "VOMITS" (victims of modern imaging technology). Pediatric urologists are often called to contribute in the prenatal evaluation and management of these patients and in many cases will carry on taking care of them for many years postnatally. A comprehensive consideration of the postnatal investigation and management of the various anomalies detected by prenatal ultrasonography is detailed in the relevant chapters elsewhere in this book. This chapter will therefore focus predominantly on the following areas of fetal and perinatal urology:

- Pathophysiology of urinary tract malformations
- Current status of fetal intervention
- Recommendations for prenatal counseling/delivery
- Pre- and post-natal findings of the most commonly detected anomalies
- A rational approach to early postnatal investigation and management, specifically following a diagnosis of antenatal hydronephrosis
- Significance of mild dilatation ("pelviectasis")

FUNCTIONAL DEVELOPMENT OF THE URINARY TRACT

Detailed embryology is beyond the scope of this chapter, and is covered elsewhere. A pivotal event in functional development occurs at around 32 days of gestation when the ureteric bud fuses with the metanephric mesenchyme to initiate the formation of excretory nephrons. Nephrogenesis proceeds by a process of reciprocal induction until the 36th week of pregnancy, with the glomeruli, proximal tubules, and loops of Henle being derived from the metanephros, whereas the collecting ducts, calyces, and renal pelves are derivatives of the ureteric bud. In man, nephrogenesis ceases at 36 weeks, and thereafter the number of nephrons remains fixed at between 0.7 and 1 million per kidney. Major developmental defects dating from the first trimester of gestation are characterized by agenesis or dysplasia (arrested differentiation that is characterized histologically by immature tubules and the presence of aberrant mesenchymal derivatives such as smooth muscle and cartilage).

URINE PRODUCTION AND EXCRETORY FUNCTION

The primitive nephrons begin to excrete urine at around the 9th week of gestation. Initially, its composition resembles an ultrafiltrate of plasma, but as gestation progresses and tubular function matures, fetal urine begins to acquire the low electrolyte, high creatinine composition that characterizes normal urine in postnatal life.[6] Fetal urinary output at different stages in gestation has been documented by ultrasonography of the fetal bladder in healthy fetuses. By the third trimester, the hourly fetal urine production is as high as 30–40 mL/h and it constitutes around 90% of the amniotic fluid[7] (Figure 3.1). In the fetus the role of the kidney lies principally in fluid excretion, since homeostatic regulation of extracellular fluid composition is undertaken by the placenta. For this reason, creatinine clearance does not provide a meaningful measure of fetal renal function. However, extrapolation of values derived from iothalamate studies in the fetal lamb suggest that the fetal glomerular filtration rate (GFR) at 36 weeks of gestation approximates to only 5% of the surface corrected adult value.[8]

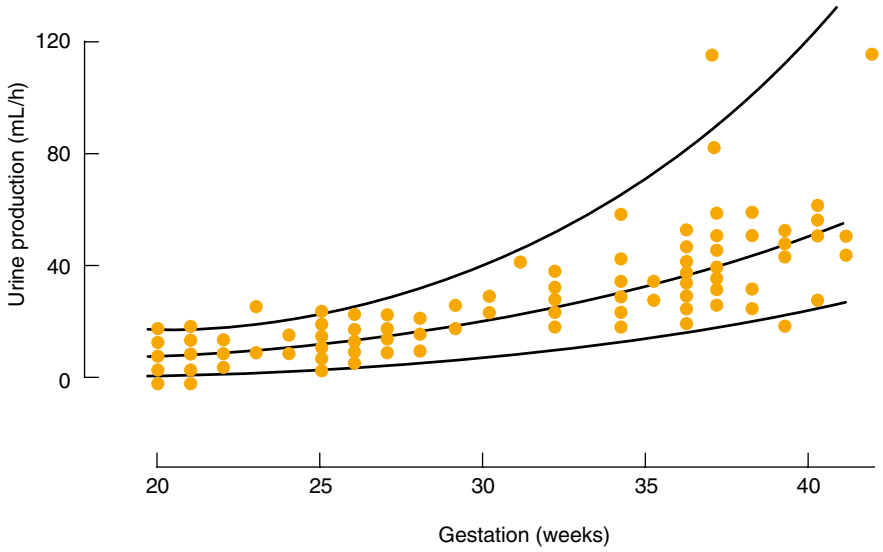

FIGURE 3.1 Fetal urine production at difference stages in normal pregnancy. (Adapted from Rabinowitz R et al. *YMOB* 1989;161(5):1264–6.)

THE KIDNEY LUNG LOOP

Amniotic fluid, of which fetal urine is the major constituent, has long been recognized as playing a critical role in lung development, and reduced amniotic fluid (oligohydramnios) is associated with varying degrees of pulmonary hypoplasia depending upon the timing and severity of the reduction in fetal urinary output. The question whether amniotic fluid plays merely a mechanical role in lung development (supported by the observation that amnioinfusion with normal saline or ringer's solution may improve pulmonary hypoplasia, especially in patients with premature rupture of membranes[9,10]) or is the vehicle for active renal-derived growth factors or other active agents remains unanswered. Severe pulmonary hypoplasia associated with bilateral renal agenesis (Potter's Syndrome) and prolonged oligohydramnios is characterized by a decrease in lung size and cell number, narrow airways, retardation of epithelial differentiation and surfactant deficiency. Furthermore, pulmonary hypoplasia can also occur secondary to lung growth restriction caused by compression of the chest cavity in the absence of amniotic fluid.[11]

CHANGES AT THE TIME OF BIRTH

In the latter stages of pregnancy the fetus maintains a physiologic state of volume expansion. A high fluid intake of swallowed amniotic fluid is matched by a high obligatory urine output. If a comparable diuresis was maintained after birth, dehydration and volume depletion would rapidly supervene, but at the time of delivery, renal physiology rapidly switches to a fluid-restrictive mode, prompted in part by high circulating levels of aldosterone, vasopressin, and catecholamines. In addition, parenchymal perfusion and GFR increase dramatically in response to a fall in peripheral renovascular resistance and greatly increased renal perfusion. But, despite these adaptive changes, renal function remains marginal, with a corrected GFR at birth averaging only 30 mL/1.73 m^2. It is not until 2 years of age that GFR reaches the normal surface corrected adult value of approximately 125 mL/1.73 m^2.

PATHOPHYSIOLOGY OF FETAL UROPATHY

Traditionally, fetal uropathy has been divided into: problems with a clear genetic background (autosomal recessive polycystic kidney disease), problems associated with defective nephrogenesis (renal agenesis, dysplasia, etc.), fetal upper and lower urinary tract obstruction and vesicoureteral reflux (VUR).

Defective Nephrogenesis

Experimental ablation of the mesonephric duct (the origin of the ureteric bud) results in ipsilateral renal agenesis.

Renal dysplasia can be caused by a number of different mechanisms, including defective interaction between the ureteric bud and metanephric mesenchyme, intrinsic defects of differentiation, and a variety of extrinsic insults, notably obstruction. The classic observational studies of Mackie and Stephens[12] demonstrated the association between ureteral ectopia, faulty induction of nephrogenesis, and renal dysplasia in duplex systems. This "ureteric bud hypothesis" can also be invoked to explain the association between renal dysplasia and high-grade reflux associated with ureteric ectopia.

In recent years, the understanding that defective nephrogenesis (i.e. renal "dysplasia") and obstruction/VUR often coexist without necessarily having a cause-effect relationship have led to the development of the terminology CAKUT—congenital anomalies of the kidney and urinary tract. CAKUT encompasses renal agenesis, hypoplasia, dysplasia, multicystic kidney dysplasia, duplication of the collecting system, ureteropelvic junction obstruction (UPJO), megaureters, posterior urethral valves (PUV)

and VUR. The incidence of CAKUT is 1/500 live births and the incidence of neonatal death caused by CAKUT is around 1/2000 live births.[13,14] The possible role for a genetic cause is supported by the observation that in about 10% of CAKUT patients, renal abnormalities are found in close relatives, albeit with great clinical variability. However, despite the identification of numerous molecular mechanisms associated with CAKUT (mutations on HNF1β, PAX2[15] and the recently described RET signaling disruption,[16] to name a few), no classical Mendelian patterns of inheritance have been demonstrated and significant modifying environmental factors are likely to play a role in the disease development process.[13]

Fetal Urinary Tract Obstruction

Upper Tract

Experimentally, even brief periods of obstruction during nephrogenesis have been shown to induce apoptosis, aberrations of cell proliferation, and trans-differentiation of mesenchyme into the phenotypes that characterize renal dysplasia. Gene expression is also disrupted by obstruction.[17] However, the results of experimentally created obstruction in animal models must be interpreted with some caution in view of the difficulty in reproducing a model of chronic, partial upper tract obstruction—the pattern most commonly encountered in clinical practice.

Lower Tract: Bladder Outlet Obstruction

Experimentally induced infravesical obstruction was extensively studied by Harrison and his colleagues in San Francisco in the 1980s.[18] For example, these authors induced partial urethral obstruction in fetal lambs at 93–107 days of gestation. They then showed that the hydronephrosis, urinary ascites, and fetal pulmonary hypoplasia, which ensued in untreated fetal lambs was reversed when the obstructed bladder was subsequently decompressed in utero. These and other studies underpinned the scientific rationale for introducing intrauterine bladder drainage in clinical practice. Unfortunately, subsequent experience with fetal intervention in the clinical setting suggests that some of the findings in the fetal lamb model may not translate to man. The current status of fetal intervention is considered in more detail below.

Fetal Vesicoureteral Reflux

The pattern of severe damage associated with grade V reflux can reasonably be ascribed to dysplasia resulting from a ureteric bud defect. By contrast, kidneys exposed to mild or moderate reflux in utero often appear normal or show global reduction in size with smooth outlines (hypoplasia) on technetium 99m (^{99m}Tc) dimercaptosuccinic acid (DMSA) imaging. Focal scarring is predominantly a feature of postnatal infection.[19]

Very little is known of the mechanisms of renal damage seen in conjunction with sterile fetal reflux but in one fetal lamb model, experimentally induced VUR has been shown to exert significant changes on tubular function and on postnatal DMSA appearances of the kidneys.[20] In addition, clinical evidence is accumulating to indicate that, even in the absence of infection, high-grade bilateral primary reflux in males carries a greater risk of renal impairment than was previously recognized.[21] While the 'water hammer' effect of sterile urine has been largely discounted as a cause of ongoing postnatal renal damage, this mechanism may exert a more significant impact in the fetus, possibly associated with high voiding pressures seen physiologically in male infants.[22]

CLINICAL SITUATIONS THAT MAY REQUIRE PRENATAL INTERVENTION

The only scenario in the realm of urology directly amenable to fetal intervention is lower urinary tract obstruction (LUTO) in males. Fetal intervention for spina bifida also has the potential to affect long-term urological outcomes and will thus be briefly discussed.

Infra-Vesical Obstruction (LUTO) in Males

It is portrayed antenatally by bilateral hydroureteronephrosis, megacystis/thick-walled bladder and a dilated posterior urethra (keyhole sign—Figures 3.2–3.4) and is most commonly caused by posterior urethral valves (PUV), although other rarer diagnoses, such as urethral atresia, prune-belly syndrome and congenital megalourethra[23] can produce similar sonographic findings (Figures 3.5 and 3.6). Megacystis can be observed as early as the first trimester of pregnancy, when it is defined by a bladder diameter >6 mm; half of the patients with early detection of megacystis will undergo spontaneous resolution. In the second trimester, megacystis is defined as an abnormally distended bladder and some authors take into account bladder emptying, defining failure to empty after 45 minutes of observation. When faced with a fetus with persistent megacystis, besides assessing the remainder of

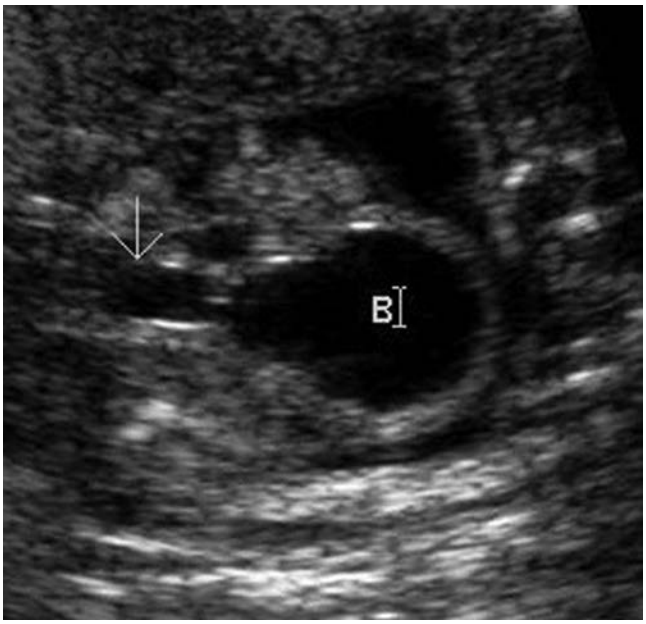

FIGURE 3.2 Keyhole sign detected early in pregnancy; "B" represents the bladder and the arrow points to the dilated urethra.

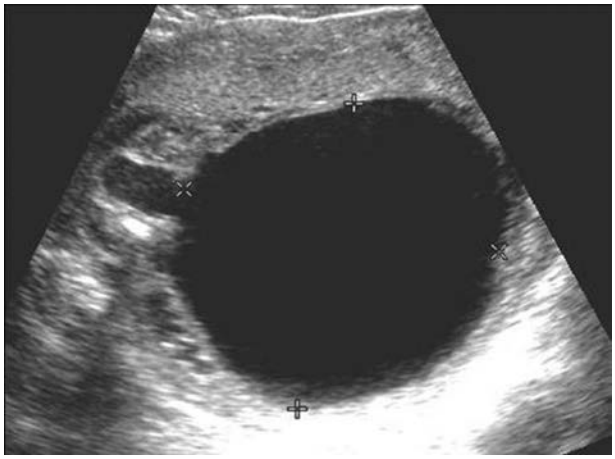

FIGURE 3.3 Megacystis associated with keyhole sign in a fetus with anhydramnios.

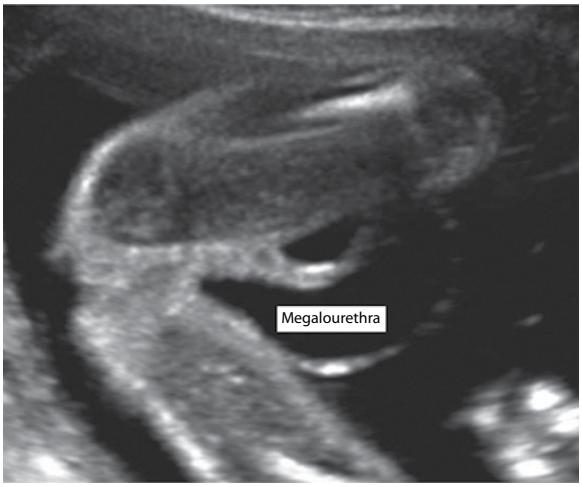

FIGURE 3.5 Prenatal sonographic appearance of congenital megalourethra.

the urinary tract for the aforementioned abnormalities associated with infra-vesical obstruction, the parents have to be advised about an increased risk for aneuploidy (as high as 25%) and associated anomalies (33%—most commonly trisomy 13 or 18). For this reason, some fetal specialists offer amniocentesis in this situation.[24] Megacystis can also be seen in the setting of megacystis-microcolon intestinal hypoperistalsis syndrome (MMIHS), a rare bowel and bladder motility disorder that affects predominantly females. Diagnosis is suggested prenatally by the association of megacystis and polyhydramnios. Patients are almost uniformly dependent on parenteral nutrition to survive and a recent literature review reported an overall survival rate just below 20%[25] (Figure 3.7).

The combination of early (<24 weeks) detection of megacystis with severe, often bilateral hydronephrosis (AP diameter >10 mm before 24 weeks of gestation), abnormal appearance of the renal parenchyma (cortical cysts, increased echogenicity) and oligohydramnios has been used as a surrogate of impaired renal function/severe infra-vesical obstruction, which will ultimately lead to pulmonary hypoplasia and fetal/neonatal demise (see Figure 3.3—massive megacystis and keyhole sign with anhydramnios). Therefore, antenatal intervention for LUTO has historically been offered to this high risk male population without evidence of other severe congenital or chromosomal anomalies.[26] An attempt has been made to correlate levels of urinary markers obtained by fetal vesicocentesis, such as sodium, calcium and β2-microglobulin with the degree of underlying renal impairment, and thus predict which patients would have a better chance of attaining acceptable renal function following prenatal relief of the obstructive component.[27] Urinary sodium > 100 mEq/L and calcium > 1.2 mmol/L appear to be the most accurate markers linked to worse renal outcomes. However, a systematic review demonstrated that none of the markers described can accurately predict poor postnatal renal function and reference values (especially for β2-microglobulin) have to be interpreted taking into account the gestational age since there is a wide variation due to changes in renal physiology.[28]

Initially, bladder decompression was achieved through open surgery, however modalities for prenatal intervention have evolved to become minimally invasive and include

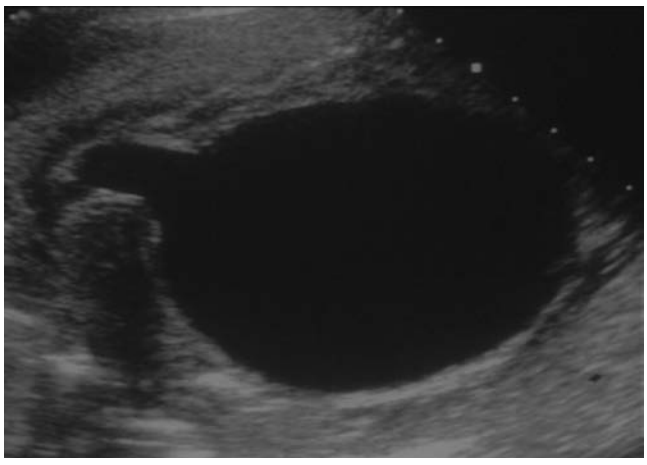

FIGURE 3.4 Megacystis and keyhole sign.

FIGURE 3.6 Postnatal appearance of infant with congenital megalourethra.

FIGURE 3.7 Megacystis associated with polyhydramnios suggesting megacystis-microcolon intestinal hypoperistalsis syndrome (MMIHS).

vesicoamniotic shunting (VAS)[29] and prenatal fetoscopic valve ablation.

VAS is the most common intervention for LUTO. It is usually performed as an outpatient procedure with maternal sedation and ultrasonography guidance. A suprapubic pigtail catheter is inserted communicating the fetal bladder with the amniotic cavity.[30,31] Dislodgement of the shunt requiring reinsertion is common[31] (Figure 3.8). Furthermore, potentially serious morbidity may arise from the procedure, such as bleeding, infection and even miscarriage (1%–2% risk).[26] Bladder and intestine herniation through a widened puncture site have been observed (Figures 3.9–3.11). Alternatively, serial infusion of normal saline or ringer's lactate in the amniotic cavity can prevent the development of pulmonary hypoplasia; this procedure, known as amnioinfusion, has been scarcely described in patients with LUTO[9] but its use is well established for

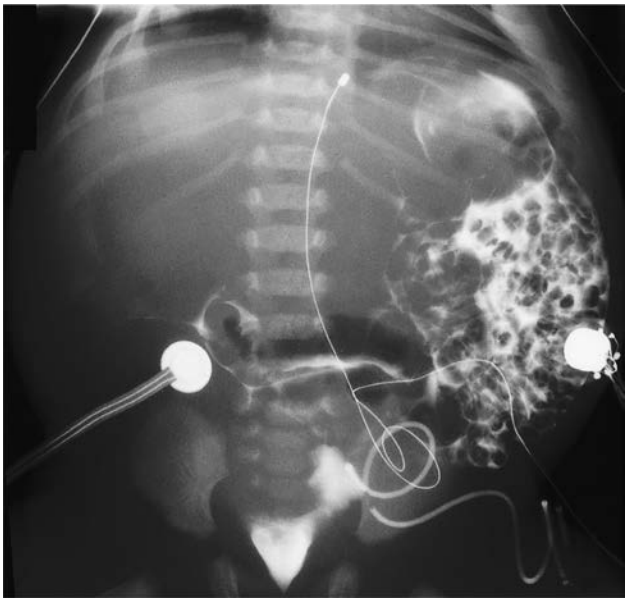

FIGURE 3.8 Complication of vesicoamniotic shunting. A postnatal contrast study reveals intraperitoneal placement of shunt with extravasation of contrast and urinary ascites. Despite shunting, this neonate succumbed to pulmonary hypoplasia.

FIGURE 3.9 Newborn with herniated bowel and vesico-amniotic shunt following antenatal intervention.

FIGURE 3.10 Newborn with prolapsed bladder following antenatal intervention.

FIGURE 3.11 Detail of prolapsed bladder following antenatal intervention.

allowing adequate lung development in patients with premature rupture of membranes.[10]

In recent years, fetal cystoscopy has been introduced as both a diagnostic and therapeutic tool in pregnancies complicated by LUTO.[32,33] It offers the advantage of allowing differentiation between PUV and urethral atresia as well as prenatal ablation of the former.[34] Notwithstanding the theoretical benefit of performing a definitive intervention with full visualization of the anatomy, a systematic review failed to demonstrate improved perinatal mortality/morbidity compared to VAS, called attention to the low quality of the reports on the subject and regarded fetal cystoscopy as "experimental" at this stage.[35]

In contrast to the evidence-based approach developed by Harrison's group in San Francisco, obstetricians in many other centers enthusiastically adopted fetal intervention on an uncritical and unreported basis in the 1980s. Where results were published, they were uniformly disappointing. The Fetal Surgery Register[36] reported an overall mortality rate of 59% in 73 fetuses—but this was probably an overoptimistic assessment, since an accurate urologic diagnosis was not established in many cases. By the end of the 1980s, enthusiasm for fetal intervention was waning. Mandell et al.[37] identified 24 related publications between 1982 and 1985, but only 7 publications between 1985 and 1989, of which two were single case reports. Medium to long-term outcome results have been reported by some centers, which continue to undertake fetal intervention on a responsible and audited basis. In Detroit, Freedman and associates[38] documented the outcome of vesico-amniotic shunting in 34 fetuses treated during the period 1987–1996. Of these, only 17 survived to term, of whom 14 were assessed after 2 years minimum follow-up. Eight of these 14 children had already progressed into end-stage renal failure and 5 had been transplanted at the time of the study. Thus, of the original total of 34 shunted fetuses, only 6 were alive with normal renal function when assessed after 2 years of age. In another long-term study, the San Francisco group[39] analyzed the late outcome of 36 fetuses treated in the period 1981–1999. All had been selected for treatment on the basis of favorable urinary biochemistry. Of the 36 treated fetuses, 14 had a diagnosis of posterior urethral valves—of whom 6 did not survive to term. However, 8 infants with prenatally detected urethral valves treated in utero did survive and were evaluated at the mean of 11.6 years—when 5 were in renal failure. In all, only 3 (21%) of the 14 fetuses with posterior urethral valves survived with normal renal function. Biard et al. reported the outcomes of 20 pregnancies with LUTO treated with VAS and followed for a mean of 5.8 years; despite the high survival rate (91%) and the findings that children were neurodevelopmentally normal and scored similar to controls in health-related quality of life questionnaires, 1/3 of the patients required renal replacement therapy (dialysis and/or transplantation) and roughly 40% intermittent catheterization for bladder management.[40] In the authors' institution, long-term follow-up data was available for 6 patients from a total of 14 who underwent VAS in the last 20 years; after a mean follow-up of 10.8 years, 3 patients had undergone renal transplantation, 1 was on renal replacement therapy and 1 was being prepared for preemptive transplantation (unpublished data). From a meta-analysis of published series totaling 342 fetuses, Clark et al.[41] concluded that "amongst controlled studies bladder drainage appeared to improve perinatal survival relative to no drainage." Nevertheless, these authors cautioned that this positive conclusion might be influenced by a subgroup of fetuses with poor prognosis who had experienced a particular benefit in terms of early survival.

In summary, if survival is taken as the endpoint, there is reasonable evidence that intrauterine intervention ("fetal surgery") is effective, probably by facilitating lung development. Unfortunately, this does not appear to be true of renal development, since a high proportion of infants who have been treated in utero nevertheless progress rapidly into end-stage renal failure—with significant implications for their quality of survival in childhood and later life. Long–term outcome studies and a growing body of anecdotal evidence indicate that fetal intervention does have the potential to increase survival by reducing the risk of pulmonary hypoplasia. By contrast, there is very little evidence that the prognosis for renal function is significantly improved by fetal intervention—probably because this is largely determined by dysplasia, which predates diagnosis and treatment.

Indeed, it seems highly likely that some infants who might otherwise have succumbed to pulmonary hypoplasia have survived as a result of fetal intervention only to progress rapidly into end-stage renal failure in infancy or early childhood. Ransley[42] has consistently argued that our perception of fetal intervention has been colored by poor outcomes in bad prognosis cases and has suggested that the potential benefits of fetal intervention might be more apparent if it was extended to include all male fetuses with evidence of outflow obstruction in the second trimester, which is the subject of an ongoing multicentric prospective randomized trial known as PLUTO (percutaneous shunting for lower urinary tract obstruction). This trial is not based on strict entry criteria but rather on the "uncertainty" principle, i.e. whenever the clinical team is significantly uncertain as to whether a male fetus with evidence of isolated bladder outflow obstruction should be shunted or not, the fetus is eligible for randomization. Furthermore, fetuses that are not randomized (either shunted or not) will be entered into a prospective registry that will allow comparison of outcomes later on. The trial predicts enrollment of 200 pregnancies (100 for each arm) and the primary outcomes are perinatal mortality and renal function at 4–6 weeks and 12 weeks of age.[30]

Finally, it is not uncommon for termination of pregnancy (TOP) to be offered to families in light of detection of LUTO associated with oligohydramnios or findings suggestive of severe bilateral renal impairment and the perspective of need for lifelong renal replacement therapy and its associated morbidity. In a multicentric European study analyzing over 700,000 births, renal malformations were diagnosed prenatally in 82% of all cases and 29% of those pregnancies were terminated.[43] In a similar study from the US targeting a population of 163,000 pregnant women, the TOP rate for PUV was 46%.[44] Nonetheless, it should be kept in mind that there is no single predictive factor with enough specificity to foresee which patients will truly have a poor renal outcome postnatally and thus support TOP, as illustrated by a study that followed 10 fetuses for whom TOP was offered based on sonographic

findings and declined; 5 died in the first month of life and all 5 survivors (2 of which had oligohydramnios) had a normal creatinine and variable degrees of proteinuria after a median follow-up of 29 months.[14]

Spina Bifida

A recently conducted randomized trial concluded that prenatal myelomeningocele repair through open fetal surgery results in improved motor outcomes and reduced need for ventriculo-peritoneal shunt placement, whilst with an increased risk of preterm delivery and maternal morbidity.[45] However, after a mean follow-up of 9.6 years, no difference was found in terms of management of the neurogenic bladder and bowel in patients who underwent fetal surgery compared to controls.[46]

CLINICAL SITUATIONS THAT WARRANT PRENATAL COUNSELING, DELIVERY IN A TERTIARY CARE CENTER AND PROMPT POSTNATAL EVALUATION, BUT NOT PRENATAL INTERVENTION

The main diagnoses in this category are autosomal recessive polycystic kidney disease (ARPKD), bladder exstrophy, cloacal exstrophy and some Prune-Belly-Syndrome (PBS) patients as well as some rare females with cloacal anomalies and hydrocolpos/secondary urinary obstruction.

With an incidence between 1:10,000 and 1:40,000 and a variable phenotype, ARPKD can be diagnosed prenatally by the findings of nephromegaly and hyperechogenicity affecting both kidneys (Figure 3.12). An empty bladder and oligohydramnios leading to Potter's Syndrome are possible, which explains the neonatal mortality rates between 30 and 50% due to respiratory insufficiency. Prenatal molecular diagnosis is now available,[47] which is key especially in cases of perinatal demise for the purpose of parental counseling, since the risk of recurrence is 25%. No prenatal intervention is available, however delivery in a tertiary care center is mandatory for advanced respiratory care as well as renal replacement therapy, which can be required as soon as the neonatal period.

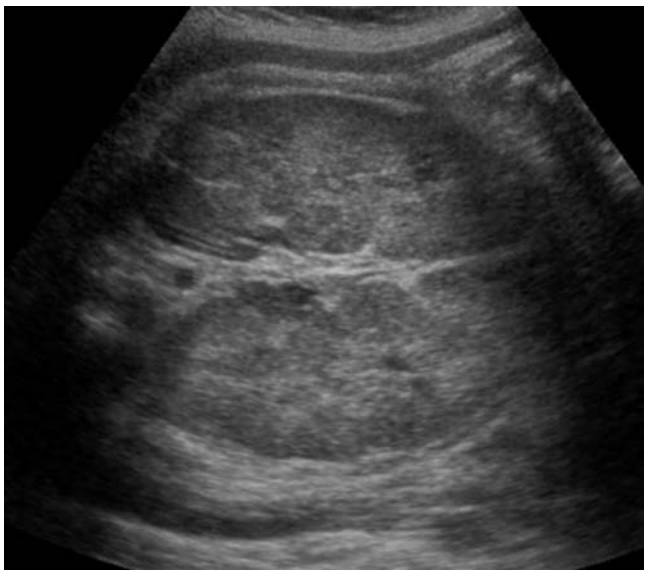

FIGURE 3.12 Enlarged, hyperechogenic kidneys at 36 weeks' gestation suggestive of ARPKD.

Antenatal detection of bladder and cloacal exstrophy can be very challenging. In a report by one of the only two centers treating these conditions in the UK, only 25% of the patients were diagnosed prenatally. Furthermore, the authors found that one of the patients referred with a prenatal diagnosis of bladder exstrophy was in fact born with a simple gastroschisis, highlighting the hazard of misdiagnosis with its catastrophic potential consequences (i.e. in case the parents had opted for TOP).[48]

Bladder exstrophy is suggested prenatally by 5 sonographic signs: absent bladder, lower abdominal bulge corresponding to the exstrophied bladder, small penis with anteriorly displaced scrotum, low umbilical insertion and widening of the iliac crests (Figure 3.13a and b).[49] Prenatal detection rates just over 50% are not as high as the ones observed for other urological anomalies.[43] Associated problems are uncommon. The main differential diagnosis prenatally is an abdominal wall defect, such as gastroschisis or omphalocele, however in either case a normally filled bladder should be identified within the pelvis.[24]

Cloacal exstrophy, also called OEIS complex (omphalocele, exstrophy, imperforate anus and spinal anomalies) is a severe congenital malformation and prenatal diagnosis is based on the association of anomalies; detection rates are similar to classic bladder exstrophy (just above 50%).[50] Usually, non-visualization of the bladder coupled with a large lower midline abdominal wall defect and a lumbar myelomeningocele will suggest OEIS. Associated anomalies within the CAKUT spectrum are commonly present[24,51] and patients sometimes succumb in utero to pulmonary hypoplasia secondary to oligo/anhydramnios. Differential diagnosis between OEIS and classic bladder exstrophy is not always straightforward, which is a source of significant anxiety for both parents and the medical team during discussions about continuation of pregnancy.

Occasionally, cloacal anomalies that do not fit into the full OEIS complex spectrum can be diagnosed prenatally as well. Prenatal US demonstrates a cystic structure in the pelvis that may be lobulated or contain debris, but sometimes can be mistaken for a megacystis in a female fetus or else a fetus with findings suggestive of ambiguous genitalia. The cystic structure corresponds to a hydrocolpos, which can cause severe secondary urinary obstruction.[52]

Fetal magnetic resonance imaging (MRI) holds promise as a confirmation test in the presence of equivocal sonographic findings for bladder exstrophy, OIES and cloacal anomalies. It provides enhanced soft tissue resolution and allows accurate gender determination, which is important for prenatal counseling of the bladder exstrophy spectrum conditions, since males will require more extensive surgical reconstructive work postnatally.[48,53]

Due to the wide variability of findings, PBS can present within the full-blown LUTO spectrum described before

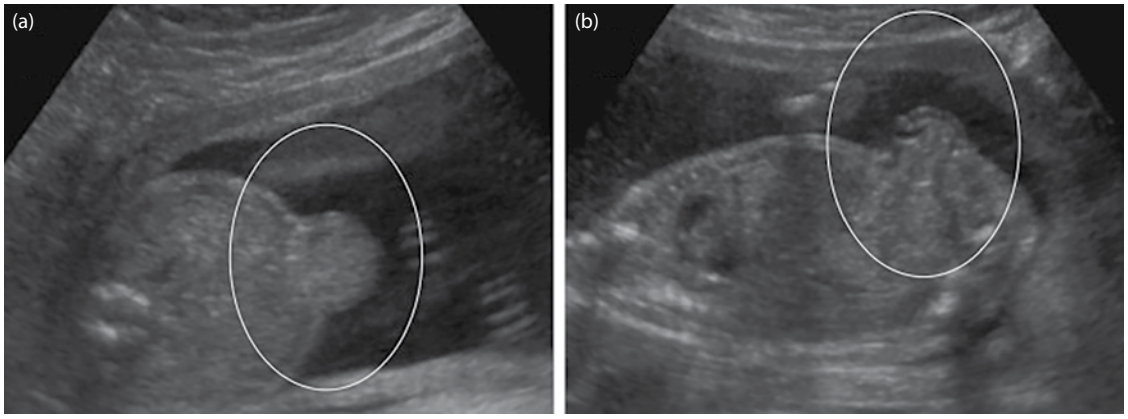

FIGURE 3.13 Prenatal ultrasound of fetus with bladder exstrophy. (a) Lower abdominal bulge is highlighted. (b) Bladder exstrophy and phallus with dorsal curvature are outlined.

or not. Possible sonographic findings are enlarged, thick-walled bladder, bilateral hydroureters with or without hydronephrosis, abnormal abdominal wall, bilateral intra-abdominal testicles and megalourethra.

Because of the inherent high complexity and potential need for medical/surgical interventions in the neonatal period, patients diagnosed with these conditions prenatally should be delivered in a tertiary care center or at the very least be transferred to one immediately after birth.

A consequence of prenatal diagnosis for these conditions, which require major reconstructive procedures and are associated with long-term morbidity, is a sharp increase in TOP rates (Figure 3.14a and b). In a review by Cromie et al., 31% and 25% of pregnancies with PBS and bladder exstrophy were terminated, respectively.[44] In an European series, 80% of bladder exstrophies detected antenatally underwent TOP.[43] Once again, the change in the scope of practice of pediatric urologists is highlighted, with more families requiring counseling and declining rates of reconstructive surgery. Particularly in the case of classic bladder exstrophy, the lack of associated anomalies and renal dysfunction, as well as the possibility of achieving reasonable quality of life with adequate postnatal care turn systematic TOP into an overly aggressive policy in

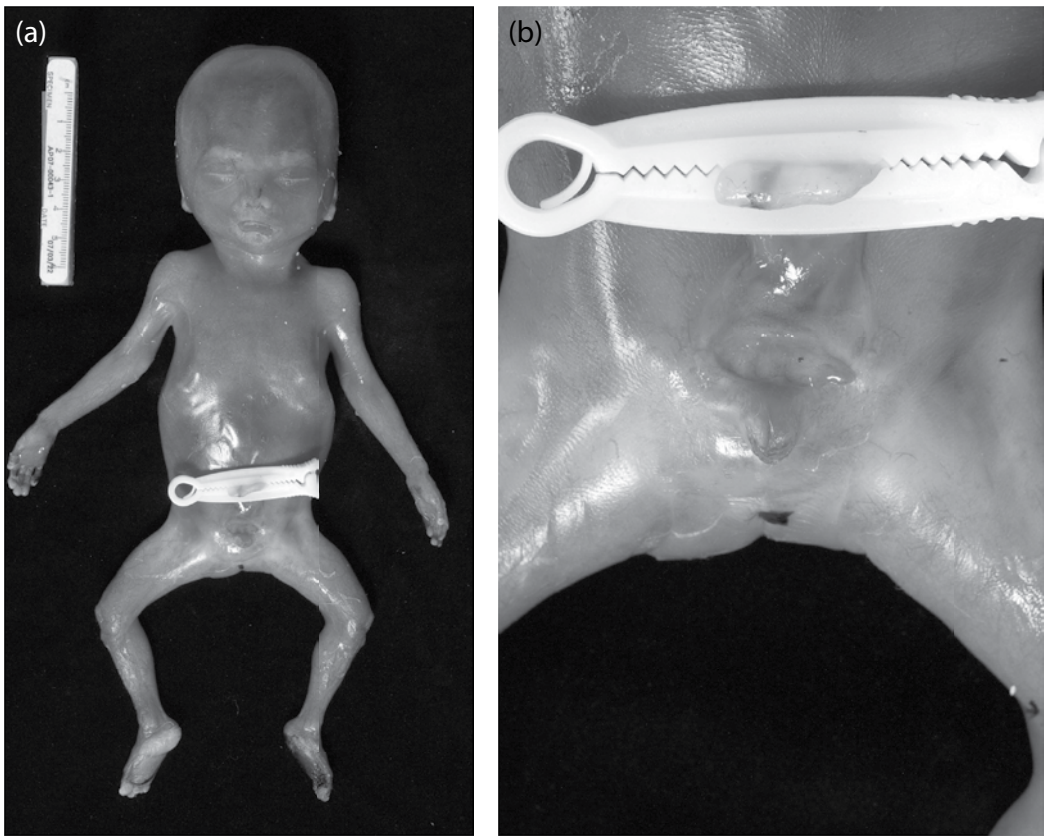

FIGURE 3.14 (a, b) Fetus with bladder exstrophy; parents opted for termination of pregnancy.

the authors' view, underlining the importance of broad and realistic prenatal advice. The importance of prenatal counseling by pediatric urologists and even other professionals experienced with the holistic management of these patients (i.e. social workers, psychologists, etc.) has to be underscored.

COMMON PRENATAL SONOGRAPHIC FINDINGS AND CORRELATION WITH POTENTIAL POSTNATAL FINAL DIAGNOSES THAT REQUIRE NON-URGENT POSTNATAL EVALUATION

The vast majority of patients diagnosed prenatally with a urological abnormality will require non-urgent postnatal consultation. This subgroup is largely represented by unilateral antenatal hydronephrosis (ANH). Ureteral dilatation, multicystic dysplastic kidney (MCDK) and duplex collecting system with its associated problems (i.e. ectopic ureter, dysplastic upper pole, ureterocele) are other conditions that fit into this category. In most situations, it will be difficult to establish a definitive diagnosis until the postnatal investigation is completed. The true benefit of prenatal diagnosis in these instances is debatable, since there is no role for intervention and a positive finding is a source of significant parental anxiety. It is challenging to determine how much information should be offered to parents, given the inherent uncertainty about postnatal outcomes. A systematic review comparing the impact of high feedback (women can see the screen and get detailed explanations about all findings) vs. low feedback (women cannot see the screen and get a brief summary at the end of the study) prenatal ultrasonography on maternal anxiety was inconclusive as to which feedback modality would improve maternal health behaviors.[54]

Dilatation of the renal pelvis (hydronephrosis) is the most common abnormality detected prenatally overall, with an incidence of 1%–5%.[5] Hydronephrosis is a sonographic finding rather than a disease per se, characterized by confluent dilatation of the collecting system; isolated dilatation of the upper urinary tract may denote active obstruction (ureteropelvic junction obstruction—UPJO) or most commonly non-obstructive, non-specific and self-resolving dilatation. Alternatively, the presence of a small kidney with minimal or no parenchyma and non-communicating cysts is highly suggestive of a multicystic dysplastic kidney (Figure 3.15). When faced with a prenatal diagnosis of hydronephrosis, the caregiver must pay attention to 2 aspects: unilateral versus bilateral dilatation and presence of other urinary tract findings. In the presence of bilateral hydronephrosis, careful consideration should be given to the lower urinary tract and the possibility of infra-vesical obstruction (see previous LUTO section). Another important aspect of sonographic evaluation is echogenicity of the renal parenchyma. Abnormally echogenic (bright) kidneys (Figure 3.16) are usually associated with dysplasia and functional compromise to variable degrees can be expected; as a parameter for comparison, echogenicity of the kidneys should be similar to that of the liver or spleen.

Quantitatively, ANH is defined based on the anteroposterior (AP) diameter of the renal pelvis, measured following a standardized method (transverse view right on the edges of the renal parenchyma to avoid overestimations by measuring the extra-renal pelvis—Figure 3.17). There is no consensus as to which measurements are clearly associated with postnatal pathology. Whereas exact cutoffs to define significant dilatation are lacking, it seems that isolated pelvis dilation <15 mm in the third trimester is hardly ever associated with postnatal pathology requiring intervention.[55] The Society for Fetal Urology (SFU) grading system is a qualitative tool used worldwide to report ANH findings as follows:

- *Grade I*: Splitting or separation of the renal pelvis (Figure 3.18)
- *Grade II*: Moderate dilatation of the renal pelvis with no calyceal dilatation (Figure 3.19)

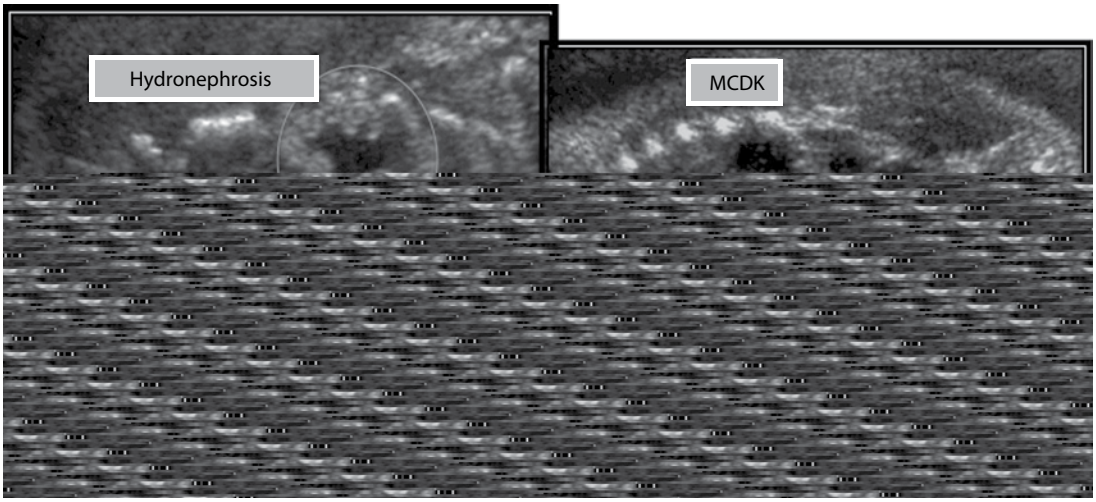

FIGURE 3.15 Comparison of hydronephrosis and multicystic dysplastic kidney appearances on prenatal ultrasound. Note that hydronephrosis is confluent whereas MCDK is characterized by non-communicating cysts.

to diagnosis and treatment becomes less invasive, there has been a shift towards being more discriminatory to request a VCUG to diagnose VUR in a patient with isolated ANH.

Both the Canadian and the American Urological Associations[62,63] guidelines recommend a VCUG for infants with antenatally detected hydronephrosis in the following scenarios:

- Isolated high-grade hydronephrosis (SFU 3-4)
- Hydroureter or bladder abnormalities on ultrasonography associated with any degree of dilatation
- After an episode of febrile UTI

Nevertheless, the SFU guidelines acknowledge that there is no evidence to support or avoid postnatal imaging for VUR[5] and the American Academy of Pediatrics has recommended against a VCUG after the first episode of febrile UTI in infants on their latest guidelines.[64] Although comprised mostly of case series with variable radiological criteria, the best available evidence is the meta-analysis by Lee et al. (1308 subjects), which demonstrated that the risk of any postnatal pathology increased with the grade of antenatal hydronephrosis from 11% for mild to 88% in severe cases, EXCEPT for VUR, found with a similar incidence across the board irrespective of the grade of ANH (around 15%).[58] Hence, the aforementioned guidelines and recommendations are not strongly supported by evidence. They are based on the assumption that higher grades of hydronephrosis can be associated with higher grades of VUR, which in turn would place such children at a higher risk for UTI.

The exact indications for a VCUG in patients with isolated hydronephrosis are truly not clear at this stage and probably would be better delineated by a proper randomized trial. Currently, the authors' recommendation is to approach each case individually, taking into account the level of understanding of the family, access to health care and specific imaging findings.

When a decision for a VCUG is made, the test should be performed under antibiotic coverage with a regular urinary catheter or feeding tube, which should be left indwelling whenever urethral obstruction is demonstrated.

Antibiotic Prophylaxis

There is evidence that patients with ANH have a substantially higher risk of pyelonephritis leading to hospitalization than the general population.[65] The incidence of febrile UTI in the ANH group has been reported in the 4%–19% range.[65–67] As summarized in the SFU consensus statement, there is some evidence that the risk increases with the severity of hydronephrosis, presence of drainage impairment and is not necessarily correlated with the presence of VUR.[5] In addition, it seems higher in girls.[65,66] In a study of 206 consecutive patients with ANH, high-grade hydronephrosis carried a 3-fold greater risk of febrile UTI compared to low-grade.[68]

A meta-analysis demonstrated that offering prophylaxis to 8 patients with SFU grades 3 or 4 hydronephrosis would prevent 1 UTI, regardless of their VUR status.[69] However, in analogy to the VCUG discussion, by using a liberal antibiotic prophylaxis policy, one has to acknowledge the large number of patients being exposed to medication (or in the previous case, radiation) unnecessarily. Again, the issue is extremely controversial and alike the indications for VCUG, would probably benefit from a randomized trial. An individualized approach is thus recommended. Evidently, when the conservative pathway is chosen (i.e. no VCUG, no antibiotics), parents should be taught to seek for immediate medical attention during an episode of unexplained fever, when a catheter urine specimen should be obtained and the child placed on antibiotics until the results are available.

Isotope Imaging

In contrast to infection, unilateral obstruction per se rarely poses an urgent threat and thus the information provided by functional imaging does not usually influence early management decisions in infancy. ^{99m}Tc DMSA is best suited for confirming total absence of function in a multicystic dysplastic kidney or for documenting differential function and patterns of parenchymal damage associated with VUR. Dynamic renography with ^{99m}Tc mercaptoacetyltriglycine (MAG3) is used primarily for the diagnosis of obstruction, including furosemide washout as an essential element of the study. Since the information derived from diuretic renography is rarely crucial in the first few weeks or months of life, this investigation can generally be deferred for 4–6 weeks.

Magnetic Resonance Urography (MRU)

MRU is a promising recent addition to the diagnostic armamentarium in patients with prenatal hydronephrosis. Its most appealing advantage is the possibility of providing high-quality anatomical and functional assessment of the urinary tract simultaneously. Some studies have also suggested that MRU would be superior to nuclear imaging studies for the diagnosis of pyelonephritis or renal scarring. An important limiting downside of MRU is the need for general anesthesia in virtually all patients under investigation for antenatal hydronephrosis. In summary, MRU holds promise for the future but is still not widely available and has not been fully incorporated to postnatal investigation protocols.[70]

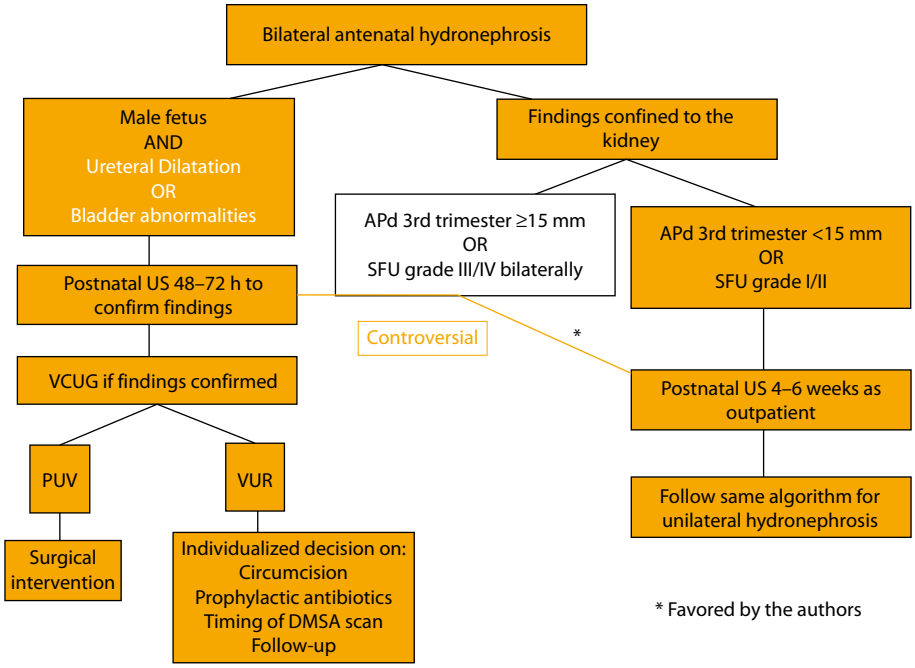
Suggested Protocols for Postnatal Investigation

Postnatal Confirmation and Initial Management of Commonly Prenatally Detected Uropathies

A detailed consideration of the investigation and management of individual urinary tract malformations appears elsewhere in the relevant chapters of this book but some of the key points can be briefly summarized as follows.

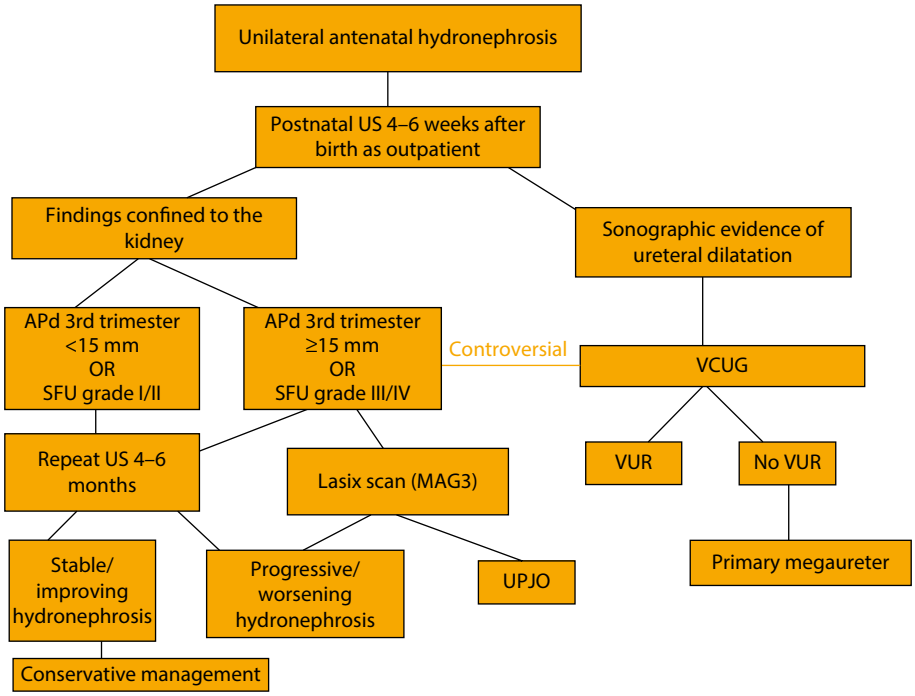
UPJO

UPJO is suspected in the setting of significant isolated dilatation that is confined to the renal pelvis. Establishing an undisputable diagnosis of obstruction is very challenging and the nomenclature is still variable



PROTOCOL 1 Suggested postnatal investigation for prenatally detected bilateral hydronephrosis. Note that highly controversial areas are highlighted with a different color. US, ultrasound; VCUG, voiding cystourethrogram; APd, antero-posterior diameter of the renal pelvis; UPJO, ureteropelvic junction obstruction; PUV, posterior urethral valves; VUR, vesicoureteric reflux.

across centers; some authors will define UPJO based solely on objective parameters such as severe hydronephrosis coupled with significant impairment in drainage and function on the diuretic renogram, thus suggesting a true component of pathologic obstruction. Conversely, others will use the term broadly for any patient with persistent hydronephrosis. The authors prefer to rely on serial ultrasonographys to establish the diagnosis of UPJO since nuclear renogram and even measurement of differential renal function have many pitfalls, i.e.



PROTOCOL 2 Suggested postnatal investigation for prenatally detected unilateral hydronephrosis. Note that performing a VCUG for isolated grades 3 and 4 hydronephrosis is controversial and the authors' preference is NOT to have a VCUG in such a scenario (please see text). US, ultrasound; VCUG, voiding cystourethrogram; APd, antero-posterior diameter of the renal pelvis; UPJO, ureteropelvic junction obstruction; VUR, vesicoureteric reflux.

orientation of the renal pelvis leading to under/overestimation of renal function.[71]

The management of prenatally detected UPJ obstruction has generated considerable controversy and the evolution of a more selective approach to surgery can be largely credited to Ransley's group[72] and Koff.[73] In addition to documenting the potential for the condition to resolve spontaneously, these and other authors have confirmed the relative safety of selective conservative management. Some of the more consistent themes to emerge from the literature are:

1. Significant loss of function which has occurred in utero does not usually recover despite relief of obstruction by pyeloplasty.
2. The probability of significant functional impairment at the time of birth or the subsequent risk of functional deterioration is linked to the severity of dilatation, with the risk of functional impairment being <10% where the AP diameter of the renal pelvis is <20 mm.
3. Conversely, an AP diameter of >35 mm denotes obstruction carrying a significant risk of functional impairment.
4. The risk of functional deterioration on conservative management is low, providing differential function in the obstructed kidney exceeds 40% and the maximum recorded AP diameter of the renal pelvis is <30 mm.

Longpre et al. demonstrated on multivariate analysis that the only predictors of low likelihood of hydronephrosis resolution and need for pyeloplasty (following strict surgical indication criteria) were grade 4 SFU (Figure 3.21) and APD (which averaged 2.9 cm in their surgical group).[74] Based on long-term outcomes data, even for patients with SFU grade 4 hydronephrosis or AP diameter > 2 cm, pyeloplasty will be required in about 50%–55% if strictly objective criteria for surgery are used (i.e. function deterioration <40% or symptoms, such as UTI or stones). Thus, even in this high-risk population, there is room for conservative management.[55]

Posterior Urethral Valves

Currently, antenatal diagnosis in the range of 70%–80% is the most common presentation of PUV in countries where prenatal ultrasonography is performed routinely. However, the true impact of early diagnosis in the natural history is yet to be defined. Results in the literature are conflicting; Ylinen et al. followed 2 groups of patients with PUV (with pre and postnatal diagnosis, respectively) and did not find differences in renal function after 10 years[75] of follow-up. On the other hand, Kousidis et al. observed a higher renal failure rate in boys diagnosed postnatally as well as a higher creatinine in the 2nd decade of life in the same group, suggesting that early diagnosis allows for therapy to be instituted more timely and thus postpone progression of renal dysfunction.[76] Finally, as mentioned earlier, the impact of TOP following prenatal diagnosis on long-term results by excluding the most severe cases should be underscored.

Vesicoureteral Reflux

Primary VUR accounts for 15%–20% of prenatally detected uropathies. In addition, low-grade non-dilating VUR may be identified as an incidental finding on a VCUG performed as part of the routine evaluation of a coexisting prenatally detected uropathy. Prenatally detected VUR is predominantly a disorder of male infant, with males outnumbering females by a ratio of up to 5 to 1.[77] Urodynamic studies in male infants with high–grade VUR have revealed marked bladder dysfunction,[78,79] which has been attributed by some authors to the legacy of transient urethral obstruction in utero—for example, by Cowper's duct cysts.

Regardless of any underlying cause, prenatally detected VUR seems to have a greater potential to resolve spontaneously than clinically presenting reflux. Reviewing the outcome of 413 prenatally detected refluxing units reported in 7 published series, Elder noted an overall figure for spontaneous resolution of 78% for grades I–III VUR and 36% for grades IV and V.[80] Conservative management was effective in the majority, with only 13% of children developing urinary infections during the course of follow-up.

In a study aimed at creating nomograms to predict annual resolution rates of primary VUR, detection on postnatal evaluation for prenatal hydronephrosis was significantly associated with earlier resolution.[81] In another publication, Caione et al. showed that bilateral high-grade VUR diagnosed in the 1st year of life was associated with a risk of chronic renal failure around 50%, regardless of the mode of diagnosis (febrile UTI vs. prenatal abnormality followed by postnatal diagnosis of VUR).[21]

Hence, as outlined in the section on "Postnatal evaluation/VCUG and Antibiotic prophylaxis", the true pathological significance of VUR detected after investigation for prenatal hydronephrosis remains elusive.

Multicystic Dysplastic Kidney (MCDK)

The introduction of prenatal ultrasonography revealed that the true prevalence of MCDK (Figure 3.15) is far higher than was previously recognized.[82,83] The natural history of prenatally detected MDKs is characterized by shrinkage or complete involution—which can also occur in utero, mimicking renal agenesis.[84] Postnatally, the diagnosis of MCDK is usually confirmed with an ultrasonography showing non-communicating cysts without renal parenchyma coupled with a DMSA confirming a solitary functioning kidney on the contralateral side.

Although there are reports of MDK occurring on a familial basis, it more commonly behaves as a sporadic anomaly. In the past, a VCUG was routinely obtained to rule out associated VUR but this approach is no longer recommended. The management of prenatally detected MDKs is considered elsewhere.

Mild Dilatation (pelviectasis)

Mild collecting system dilatation (Figures 3.18 and 3.19), typically a renal pelvic diameter in the range 5–10 mm, is a feature of approximately 1:100 pregnancies. However, this is often a transient phenomenon. For example, Sairam[85] reported an 80% resolution rate for dilatation in the range 4–6 mm. Likewise, Chitty et al[86] followed 475 fetuses with mild dilatation detected between

16 and 26 weeks' gestation, and documented complete resolution or improvement in 66% on re–evaluation in the third trimester. Pelviectasis is sometimes cited as a possible marker for aneuploidy. However, in a study of 25,586 unselected low–risk pregnancies, Havutcu et al[87] documented a 1.25% incidence of mild dilatation (mean AP diameter 6.4 mm, range 5–15 mm) but found no cases of aneuploidy. These authors concluded that the risk (of aneuploidy) in isolated fetal pyelectasis in low–risk populations is so small that it should not be an indication for invasive prenatal karyotyping. Although the weight of reliable evidence indicates that isolated dilatation is not a marker of aneuploidy, when this finding occurs in conjunction with other anomalies it is more strongly indicative of an underlying genetically determined anomaly or syndrome.

In summary, as detailed in the previous sections, low-grade (1 and 2) SFU dilatation confined to the renal pelvis or AP diameter <1.5 cm represent a finding of low significance that maybe does not require additional tests or investigations.[55] Late worsening or recurrent hydronephrosis has been described ranging from 1 to 5%, but the optimal length of sonographic follow-up required (if any) for such patients has not been determined in a proper study.[5]

Megaureter

Unilateral hydroureteronephrosis (Figure 3.22) that is not associated with VUR is likely secondary to primary megaureter. Discussing the classification and management of megaureter is beyond the scope of this chapter but the possibility of obstruction at the ureterovesical junction (UVJ) and consequent renal function deterioration is concerning, similarly to what is seen with UPJO. Therefore, postnatal investigation will usually entail repeated ultrasonographys, a VCUG and a nuclear scan at least to follow the differential function. The accuracy of functional studies with furosemide for obstruction in this scenario is debatable and will be addressed elsewhere. The majority of patients with non-refluxing megaureter will experience spontaneous resolution. Higher grades of hydronephrosis and larger ureteral diameters (above 1cm) are associated with lower resolution rates and higher need for surgery.[88,89]

Duplicated Collecting Systems/Ectopic Ureters/Ureteroceles

The prenatal suspicion of a duplicated collecting system (Figure 3.23) does not mandate any particular action. However, it is important to keep in mind the pathological entities that can present in association with duplication. Hence, the presence of a dilated ureter and segmental dilatation of the (upper) collecting system may denote an ectopic ureter. Alternatively, the presence of a cystic lesion in the bladder (Figure 3.24), which can be associated with ureteral dilatation and upper pole hydronephrosis as well, is suggestive of an ureterocele. The vast majority of patients with antenatally detected ureteroceles are managed postnatally in a non-urgent fashion.

FIGURE 3.23 Segmental hydronephrosis suggesting the presence of a duplicated collecting system.

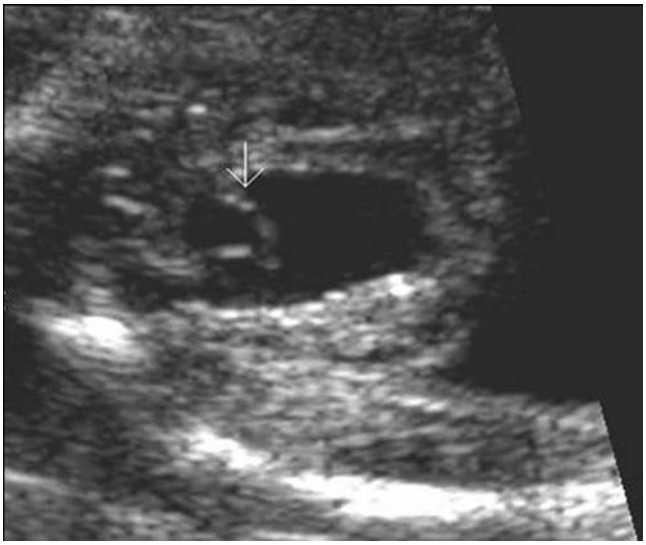


FIGURE 3.24 Finding of cystic lesion within the bladder, which is suggestive of a ureterocele.

Exceptions to that rule are patients with large ectopic ureteroceles causing bladder outlet obstruction (thus mimicking PUV[90]) and prolapsed ureteroceles in females, which may require urgent decompression (Figure 3.25a and b). Although exceedingly rare, prenatal diagnosis of prolapsed ureteroceles with fetal MRI has been described.[91]

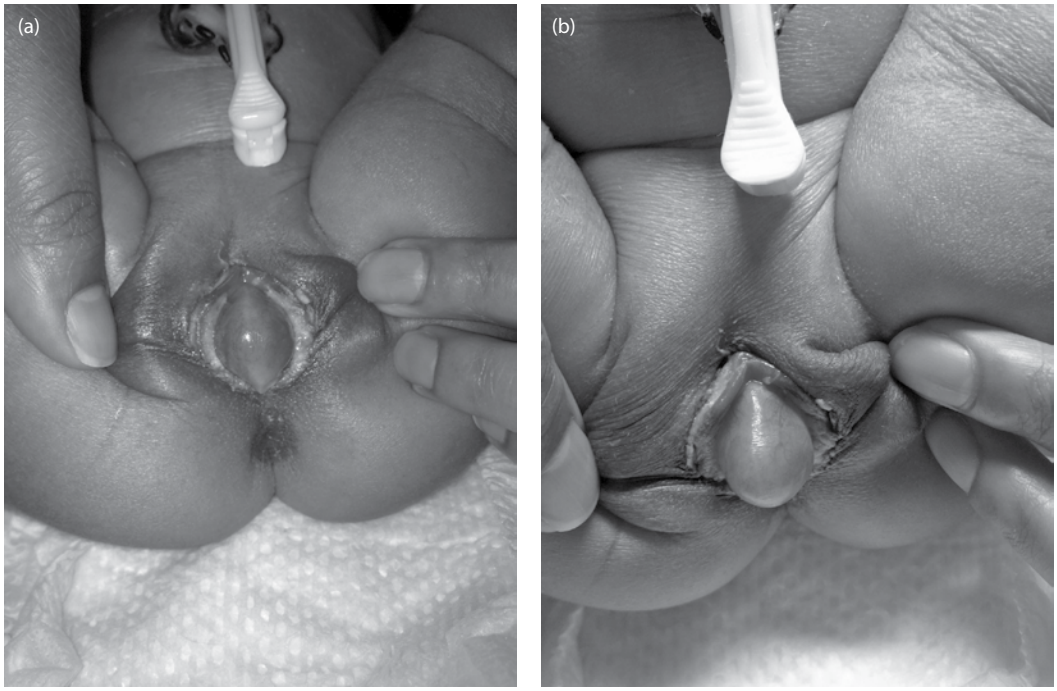

FIGURE 3.25 (a, b) Prolapsed ureterocele in a female neonate; treated with bedside puncture.

CONCLUSIONS

Ultrasonography is now so firmly rooted in obstetric practice that it would be unthinkable for pediatric urology to return to the pre-ultrasonography era. In general, prenatal diagnosis must be considered to have been beneficial, but it must also be acknowledged that the detection of mild dilatation and some asymptomatic anomalies has generated needless parental anxiety and unnecessary investigation. In many countries the impact of termination of pregnancy is already evident in a substantial decline in new cases of prune belly syndrome, cloacal and 'classic' bladder exstrophy and neuropathic bladder associated with open meningomyelocele. As termination of pregnancy extends to include other severe, nonlethal fetal uropathies the number of infants and young children requiring renal replacement therapy and transplantation (predominantly males with urethral obstruction and renal dysplasia) may also diminish.

Prenatal ultrasonography has undoubtedly advanced our understanding of the functional development of the urinary tract and the pathophysiology of many urinary tract malformations. In the future, this will be complemented by important discoveries within the rapidly advancing science of developmental biology to provide pediatric urologists with a much greater understanding of the scientific foundations of the specialty.

Prenatal diagnosis has impacted Pediatric Urology as a specialty uniquely and should encourage the execution of multicentric, prospective, high-quality long-term outcome studies to delineate the exact natural history of many of the problems that are detected, clear indications for prenatal intervention as well as indications for postnatal investigations and treatment.

ACKNOWLEDGEMENT

The authors acknowledge the contribution of Dr. Greg Ryan, Head of the High Risk Pregnancy Center at the Mount Sinai Hospital, University of Toronto, with many of the antenatal cases and figures presented in this chapter.

CHAPTER

4

In-Office Ultrasonography

Dennis B. Liu and Max Maizels

INTRODUCTION

With technical advancements leading to ever more compact, portable, and less expensive ultrasound units, pediatric urologists have increasingly incorporated ultrasonography into their office practices. Because it gives accurate information quickly, noninvasively, and without x-ray radiation, ultrasound has become a standard, initial diagnostic test to evaluate pediatric urology patients. Previously, we have shown the practicality and benefits of this modality[1–3] and now update this experience. In this chapter, we show how in-office ultrasound (IOUS) advances office practice in the initial evaluation and follow-up of a variety of common pediatric urology office scenarios.

ADVANTAGES OF IOUS IN PEDIATRIC UROLOGY

Referrals to evaluate hydronephrosis, urinary tract infections (UTIs), and enuresis (or dysfunctional elimination) account for approximately 40% of office pediatric urology consultations. Traditionally, initial evaluation begins with a comprehensive office history and physical examination, and referral to a radiologist for a conventional ultrasound exam. IOUS offers several advantages over this traditional approach. As an ultrasound exam may be included in the initial office evaluation, by performing an IOUS, the information derived leads to making working diagnoses and management plans more quickly. It reduces the need to obligate parents for return visits to the urologist after an exam performed off site in a radiology department and allows the opportunity to immediately build physician–patient–family interaction. This opportunity allows better communication with the patient and their families, thus reducing their anxieties and providing them a better understanding of the disease processes. A real-time explanation of the images by the urologist performing the exam to the parents present during the exam solidifies this physician–patient bond. Because the pediatric urologist, as the ultrasound examiner, has the clearest insight into the reason for the exam, this often leads to more exacting diagnoses, as the pediatric urologist will be able to sharply focus the examination performed as an IOUS. For example, bladder dynamics have direct influence on the status of the kidneys. Recognizing this relationship, a pediatric urologist would be able to assess the kidneys with both a full and an empty bladder, often providing more information than images performed by a nonurologist, where examination may not have included this consideration.

PERFORMING IN-OFFICE ULTRASONOGRAPHY

This chapter provides an introduction to perform and utilize ultrasonography for pediatric urology. If you would like a more comprehensive educational experience in IOUS, please visit www.cevlforhealthcare.org.

A wide variety of portable, office-based ultrasound units are available commercially, ranging from large units requiring a wheeled cart to briefcase-sized units and, most recently, handheld devices. In our practice, we use a toaster-sized sector scanner on a wheel cart at our hospital-based office and transport a briefcase-sized unit to satellite offices. We currently perform examinations with either a 5 or 7 MHz probe. For examination of the kidneys of older, larger patients, a low-frequency (3 or 5 MHz) probe is used due to its better tissue penetrance. A higher-frequency probe (7.5 or 10 MHz) is used to image closer objects, such as kidneys and bladders of younger children. Real-time images are displayed on the monitor, and hard copies of the examination may be captured onto flash memory cards or printed directly onto thermal archival paper. Printed images are kept in the patient's charts, allowing the pediatric urologist quick access to the images on subsequent office visits.

A good ultrasound examination requires a calm, cooperative, and still patient. This can be challenging in the pediatric population. The process of preparing the child for the examination begins the moment the child enters the exam room, and thus the room should be warm. The child's clothes can be loosened without disrobing. Adapting a DVD player or tablet computer to the examining platform can be helpful to engage and distract children from the fear engendered from viewing high-tech hospital equipment. Infants can be breast- or bottle-fed, allowing examination of a lulled child. Toddlers frequently fixate on the cartoons playing on the DVD player or tablet. Engaging them in simple word games may distract adolescents. The routine of placing a small terry cloth protective towel over the patient's underwear becomes "like an apron we use to help in the kitchen." Applying ultrasound gel becomes "like sun tan lotion we apply at the pool." Furthermore, warming the gel prior to use with a self-heating unit keeps the child comfortable. Older children

may be offered the opportunity to hold the transducer themselves. Very apprehensive children may be reassured by allowing their parent to apply the ultrasound gel, and the parent can hold the transducer as if he or she is performing the exam with the pediatric urologist manipulating the probe "behind the parent." Other useful tricks can be developed using your own imagination.

For brief instructions on performing an IOUS, please see Video 4.1.

POSITIONING THE PATIENT

Imaging of the Kidneys

We typically begin IOUS by positioning the child supine. Renal imaging in the supine position begins by placing the transducer anteriorly in the right or left subcostal region. The kidneys are imaged through an acoustic window provided by the liver (right kidney) or the spleen (left kidney). If the kidneys are not easily imaged subcostally, intercostal placement of the transducer may help, although pushing here may be uncomfortable and derail the exam. Alternatively, the child may be placed in the lateral decubitus position. In a toddler or youth, this is accomplished by asking the supine child to grab his or her opposite elbow, which causes them to rotate their trunk themselves. If the kidney is "hidden" by an overlying rib, assuming the prone position will provide better images. The prone position also provides a more accurate measure of length, especially when the kidneys are sequestered under a rib. To image the kidney from the prone position, the transducer is placed along the line of a dorsal lumbotomy incision to provide a longitudinal image, or perpendicular to the line to provide a transverse image of the kidneys.[2] In younger and uncooperative children, IOUS may also be performed using a posterior approach, with the caregiver embracing the child. Sometimes, a child fearful of lying supine can be examined effectively while he is standing. Posterior views are obtained.

Imaging of the Bladder and Ureters

Imaging of the bladder is best performed with the child supine. The probe is placed above the pubic symphysis and aimed at the coccyx. Rotating the probe then provides a transverse or sagittal view of the bladder. If dilated, the ureters can be seen "behind" the bladder on transverse views.

To image the ureters longitudinally, the probe is positioned parasagittally, aiming at the opposite half of the pelvis. Thereby, the *right* parasagittal scanning of the bladder displays a sagittal view of a dilated *left* ureter, and vice versa for the *right* ureter. In this view, assessment of the rectum for constipation and the internal genitalia may also be performed.

Common practical experiences of IOUS in office pediatric urology include:

KIDNEY

IOUS is ideally suited to evaluate the kidneys for hydronephrosis, renal length, and duplication anomaly.

Normal Kidney

The normal kidney is readily identified on sonography due to its sharp demarcation from surrounding structures. This sharp demarcation is due to the sonographic interface between the renal capsule and the surrounding perinephric fat. The shape of the kidney is ellipsoid in the longitudinal view (Figure 4.1). Renal length is optimally measured using this view. The normal length of the kidney in the child is dependent on multiple variables, including the side of the kidney and the child's gender, height, weight, race, and age[4,5] (Figure 4.2). In the transverse view, the kidney appears ovular. The renal cortex is typically uniform in appearance and less echogenic than the liver and spleen. In children, the renal medulla (pyramid) is sonographically more prominent than in adults and appears as hypoechoic "pockets" between the renal cortex and the renal sinus, like "seeds in a watermelon." Prominent renal pyramids can occasionally be confused with hydronephrosis, especially in the neonate. This confusion can be avoided by checking if the sonolucencies communicate with the pyelocalyceal architecture (Figure 4.3a). Hypoechoic renal pyramids do not communicate with the renal pelvis, while dilated minor calyces, evident in hydronephrosis, are confluent with the renal pelvis (Figure 4.3b). The hilum is highly echogenic, often referred to as the *central renal complex* (CRC), containing the hilar vessels and fat. To better understand the spatial relationship of ultrasound with the genitourinary system, please view Video 4.2.

Hydronephrosis

IOUS is the workhorse to approach the diagnosis and management of hydronephrosis. Hydronephrosis appears sonographically as sonolucent cavitation of the CRC. Hydronephrosis is graded according to the Society for Fetal Urology (SFU) classification system.[6] This classification system grades hydronephrosis by categorizing the pattern and extent of renal pelvic and calyceal dilation, as

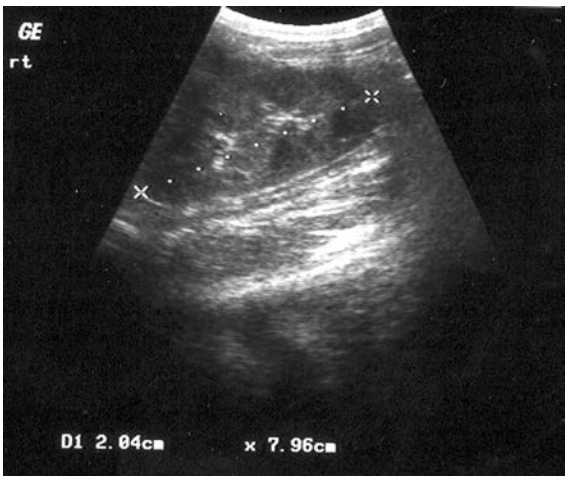

FIGURE 4.1 IOUS. Normal kidney. Longitudinal view of a normal kidney of a 3-year-old boy was done for sibling screening of VUR. The renal length is 80 mm (normal mean, 70 mm ± 10). The CEC is prominent because of its normal echogenicity. There is no hydronephrosis.

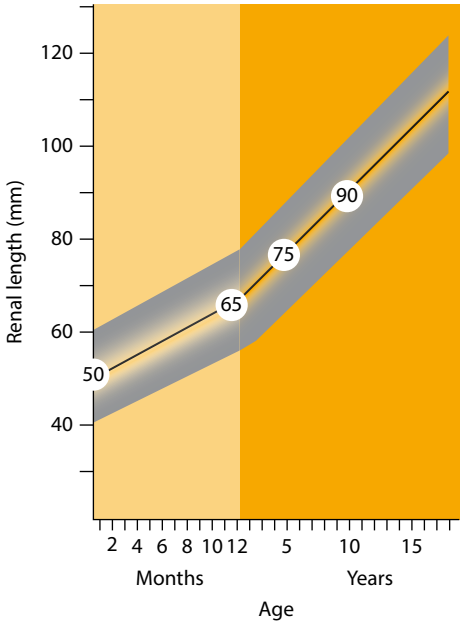

FIGURE 4.2 Nomogram for normal renal size in children. (From Han BK, Babcock DS. *AJR Am J Roentgenol* 1985;145:611–6.)

TABLE 4.1 SFU classification of hydronephrosis

Grade 0	No pelvic dilation. Renal pelvis is empty. Echogenic hilar fat is not split by retained urine.
Grade 1	Minimal pelvic dilation (minimal retention of pelvic urine evident as a thin sonolucent stripe). No calyceal dilation.
Grade 2	Moderate pelvic dilation (broad intrarenal sonolucent stripe, or an extrarenal pelvis). Major calyces may be imaged but are not considered dilated. No minor calyceal dilation.
Grade 3	Large pelvis, dilated major calyces, and minor calyces *uniformly dilated*. Normal parenchymal thickness.
Grade 4	Exaggeration of Grade 3 *with* thin parenchyma.

Source: Fernbach SK et al. *Pediatr Radiol* 1993;23:478–80.

well as renal parenchymal thickness (Table 4.1, Figure 4.4). Hydronephrosis detected on IOUS may be caused by ureteropelvic junction obstruction (UPJO), vesicoureteral reflux (VUR), obstructed upper-pole moiety ureters (ectopic or ureterocele) of a duplex collecting system, high bladder pressure (e.g., neuropathic bladder), or lower urinary tract obstruction (e.g., posterior urethral valves). On the other hand, SFU Grade 2 hydronephrosis may represent a variant of normal as an extrarenal pelvis (Figure 4.4).

As prenatal ultrasound examinations become more common in obstetrical practice, referrals to pediatric urologists to evaluate prenatally detected pyelectasis are becoming more frequent. The degree of prenatal pyelectasis that is clinically significant in predicting postnatal urologic significance has yet to be agreed on. In the postnatal evaluation of prenatally detected hydronephrosis, ultrasound examination is done after newborn discharge, at about 1 week of age. Common postnatal outcomes of prenatally detected hydronephrosis include spontaneous resolution, or the identification of VUR or UPJO. Even if IOUS demonstrates resolution of bilateral prenatally detected hydronephrosis, the child still has a 10%–30% likelihood of occult VUR[7] (Figure 4.5a,b). In this situation, IOUS provides an opportunity for immediate counseling. IOUS also plays an important role in structuring the management and follow-up of prenatally detected hydronephrosis.

Due to its convenience for performing serial exams, IOUS is an ideal modality to follow patients whose parents or family choose observational management for prenatally diagnosed hydronephrosis. In a portion of these patients, hydronephrosis will improve and the child will avoid unnecessary operative intervention (Case 1). When evaluating newborns for hydronephrosis, it is important to delay ultrasound imaging for a few days after birth,

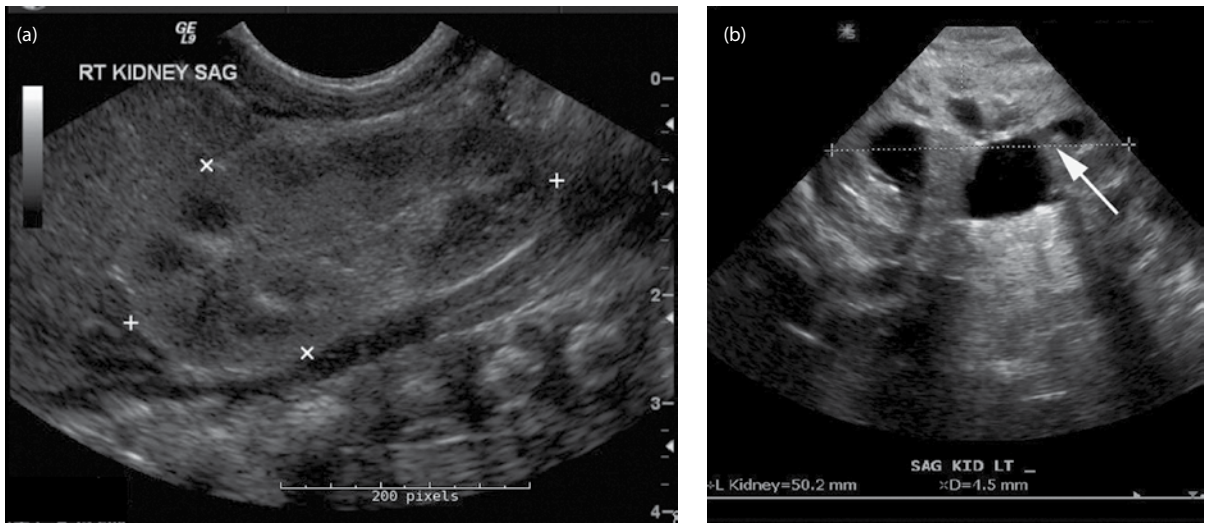

FIGURE 4.3 IOUS. Normal renal pyramids. Longitudinal view of a normal kidney of a 3-month-old girl demonstrates the sonographically prominent renal pyramids in children (a). There is no connection to the renal pelvis. (b) In contrast, there is a connection between the sonolucency and the renal pelvis (arrow).

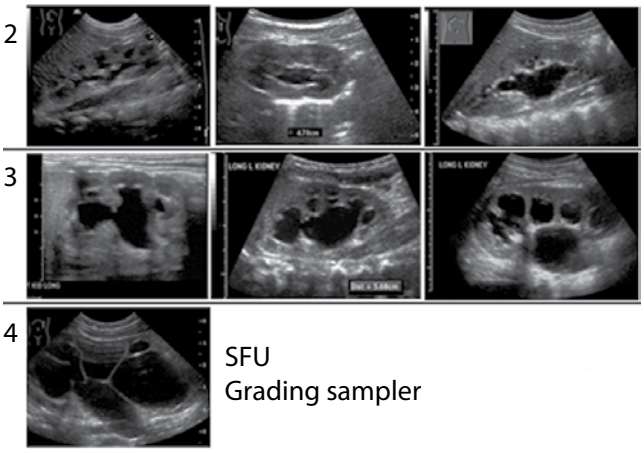

FIGURE 4.4 SFU classification of hydronephrosis. Representative images of kidneys with SFU Grades 2–4. SFU 0 and 1 are intentionally omitted.

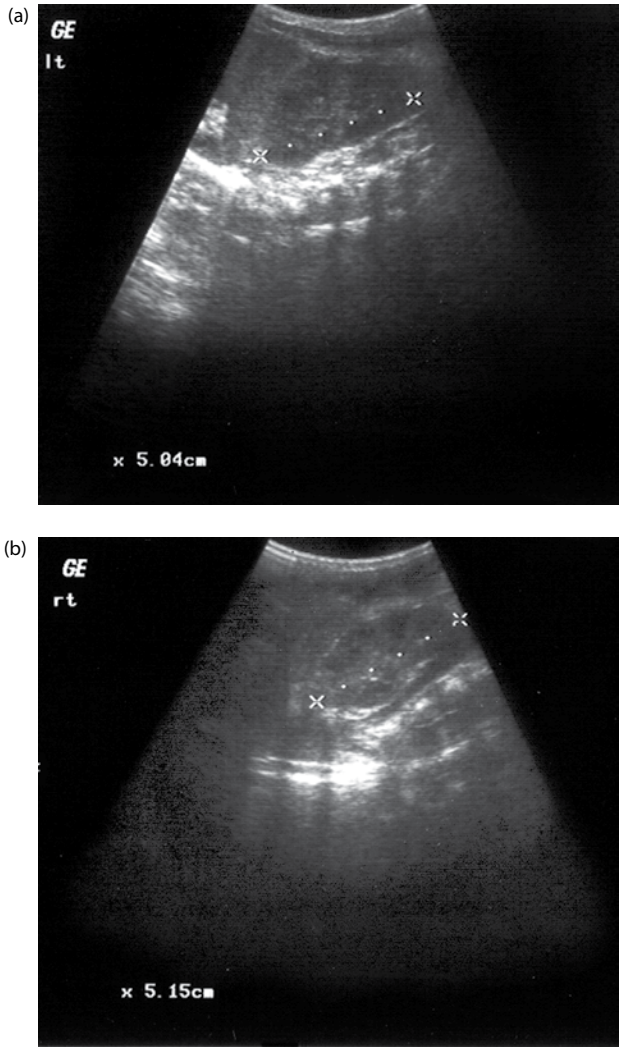

FIGURE 4.5 IOUS is used to follow up prenatally detected hydronephrosis. At 10 days old, the left (a) and right (b) kidneys are normal. These findings correlate with an 80% likelihood of a normal variant and a 20% likelihood of VUR.

as the initial postnatal ultrasound may fail to appreciate hydronephrosis due to the relative dehydration of the neonate.[8,9] Such imaging can be conveniently and expediently done with IOUS once the infant has been well hydrated. Case 2 is a demonstrative illustration of the importance of delayed imaging for Sonographically evident renal pelvis (SERP) by IOUS.

Case 1: IOUS identifies the resolution of fetal hydronephrosis (see Figure 4.6).

Case 2: IOUS is used to follow up premature ultrasonography for fetal hydronephrosis (see Figure 4.7).

In addition to UPJO, hydronephrosis may also be due to VUR. In order to evaluate for VUR, examination of hydronephrosis with both a full and an empty bladder should be performed, as the status of bladder filling directly impacts the appearance of the upper urinary tracts. The following two cases demonstrate the utility of IOUS in providing a more thorough evaluation of hydronephrosis by allowing the examiner to evaluate the upper urinary tracts with both a full and an empty bladder. In both of these cases, the hydronephrosis improved with bladder emptying, and thus dilation is more consistent with VUR than renal obstruction. Because of IOUS, the diagnosis of VUR rather than UPJO was made correctly and without further radiographic testing. By referring patients to radiology for ultrasounds, control of the examination leaves the urologist and often leads to imaging of the kidneys without regard to the status of the bladder fullness. In Case 5, not taking the state of bladder fullness into consideration may have led to an erroneous diagnosis of UPJO.

Case 3: IOUS shows fetal hydronephrosis likely related to VUR (see Figure 4.8).

Case 4: IOUS shows the importance of considering the extent of bladder fullness on hydronephrosis (see Figure 4.9).

Similarly, IOUS provides an important adjunct to evaluate hydronephrosis during the performance of videourodynamics. When performing videourodynamics, the severity of the hydronephrosis can be assessed at varying degrees of bladder fullness and detrusor pressures. This can provide the clinician with important information on the underlying etiology of the hydronephrosis. IOUS performed during videourodynamics is especially important when assessing patients born with posterior urethral valves in whom there is persistence of bilateral hydronephrosis, which may be due to either VUR or elevated bladder pressures.[10,11] Thus, patients with hydronephrosis secondary to elevated bladder pressures would benefit from institution of clean intermittent catheterization to protect their upper tracts.

Case 5: IOUS is an additional dimension to videourodynamic testing (see Figure 4.10).

Anatomic Anomalies

In addition to its role in evaluating hydronephrosis, IOUS is useful to diagnose and structure the management of a variety of anatomic anomalies. Anomalies that can be readily detected by IOUS include duplex collecting

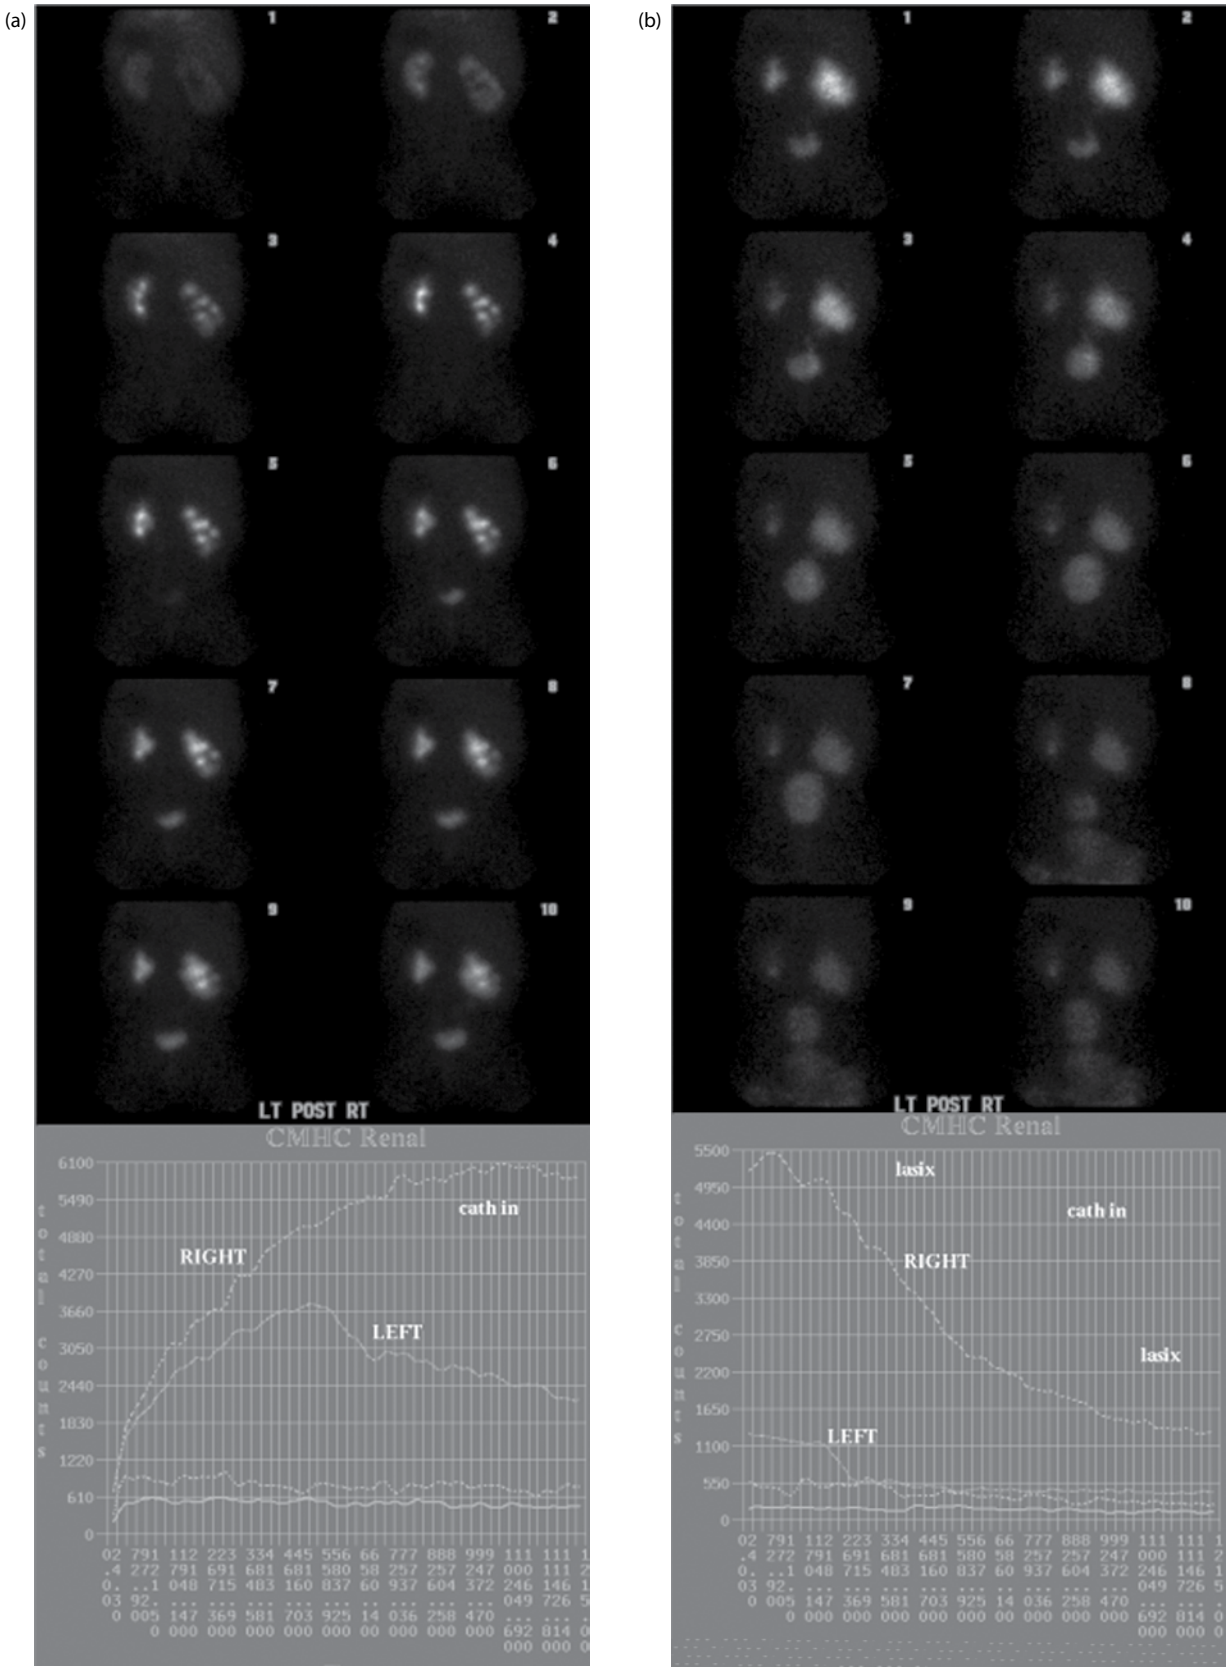

FIGURE 4.6 IOUS identifies the resolution of fetal hydronephrosis. IOUS was done to follow up fetal hydronephrosis. The newborn in-hospital ultrasound shows SFU Grade 4 hydronephrosis (not shown). (a) A diuretic renogram shows the preserved percent differential function in both kidneys with (b) t1/2 drainage = 8.5 minutes. The parents chose observation rather than surgery. (*Continued*)

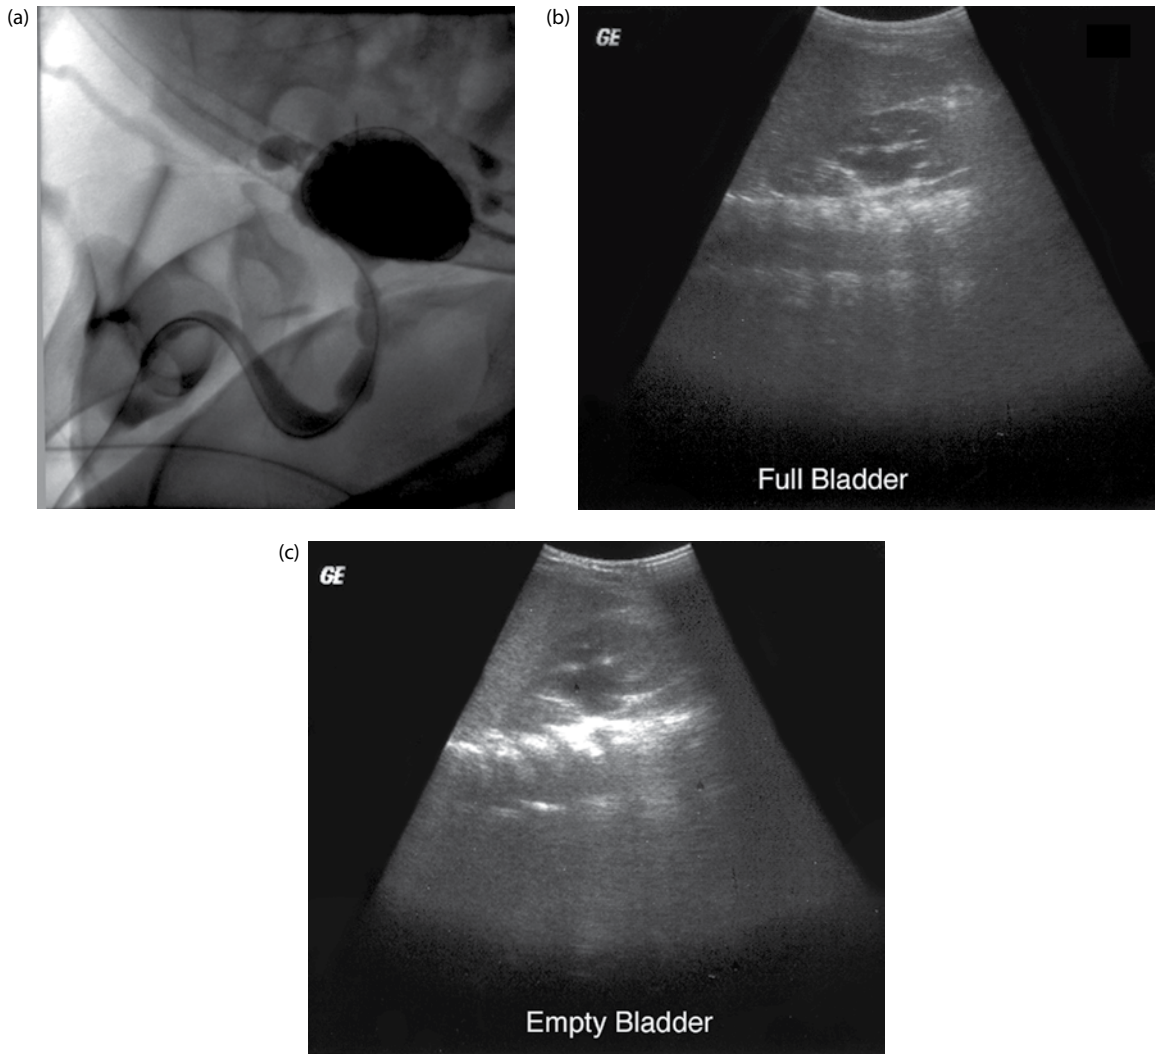

FIGURE 4.10 IOUS is an additional dimension to videourodynamic testing. A 9-month-old boy is status post newborn ablation of posterior urethral valves. Bilateral hydronephrosis persists. (a) The cause for the persistent dilation was not persistent PUV, as the urethra is open on voiding cystourethrogram, or reflux, as the cystogram is normal. IOUS is done simultaneously with videourodynamics to assess if bladder filling increases bladder pressure and so accounts for the renal dilation. IOUS shows stable SFU Grade 3 of the right kidney with the bladder both (b) full and (c) empty. Bladder pressures were less than 40 cm H_2O. The baby has continued to thrive with no further treatment. As the urological testing is normal, it is likely the hydronephrosis will gradually involute over the next 2 years.

Clinical Decision Making in the Management of Vesicoureteral Reflux

The American Urological Association (AUA) guidelines recommend an ultrasound be performed at the initial evaluation of a child with VUR and every 12 months during follow-up. Furthermore, the VUR guidelines deemed ultrasound an option to identify renal scarring in the sibling of a child with VUR, which would then provide rationale for further investigation with cystography.[15] Thus, IOUS, with its inherent advantage of convenience, provides an optimal modality in evaluating and managing patients with VUR.

Postpyeloplasty

In the setting of pyeloplasty, IOUS is used to check for resolution of hydronephrosis, which is typically seen within 2 years postoperatively, and normalization of elongated kidney length, which is typically seen within 5 years postoperatively. Postpyeloplasty imaging with IOUS showing stabilization or improvement of hydronephrosis provides reasonable reassurance of a successful procedure.[16,17] Should IOUS show upgrading of hydronephrosis, especially after the initial ultrasound at 1 month, IOUS is then useful to direct referral for a more complete evaluation with either diuretic renogram or retrograde pyelogram. We perform IOUS to check for a gradual decline in hydronephrosis postpyeloplasty at 1 month, 6 months, 1 year, 2 years, and 5 years postoperatively.

Case 11 (see Figure 4.15).

Postdetrusorrhaphy

Success rates for surgical repair of VUR are approximately 80%–99%.[18] The potential complications of detrusorrhaphy include persistent VUR, new-onset contralateral VUR,

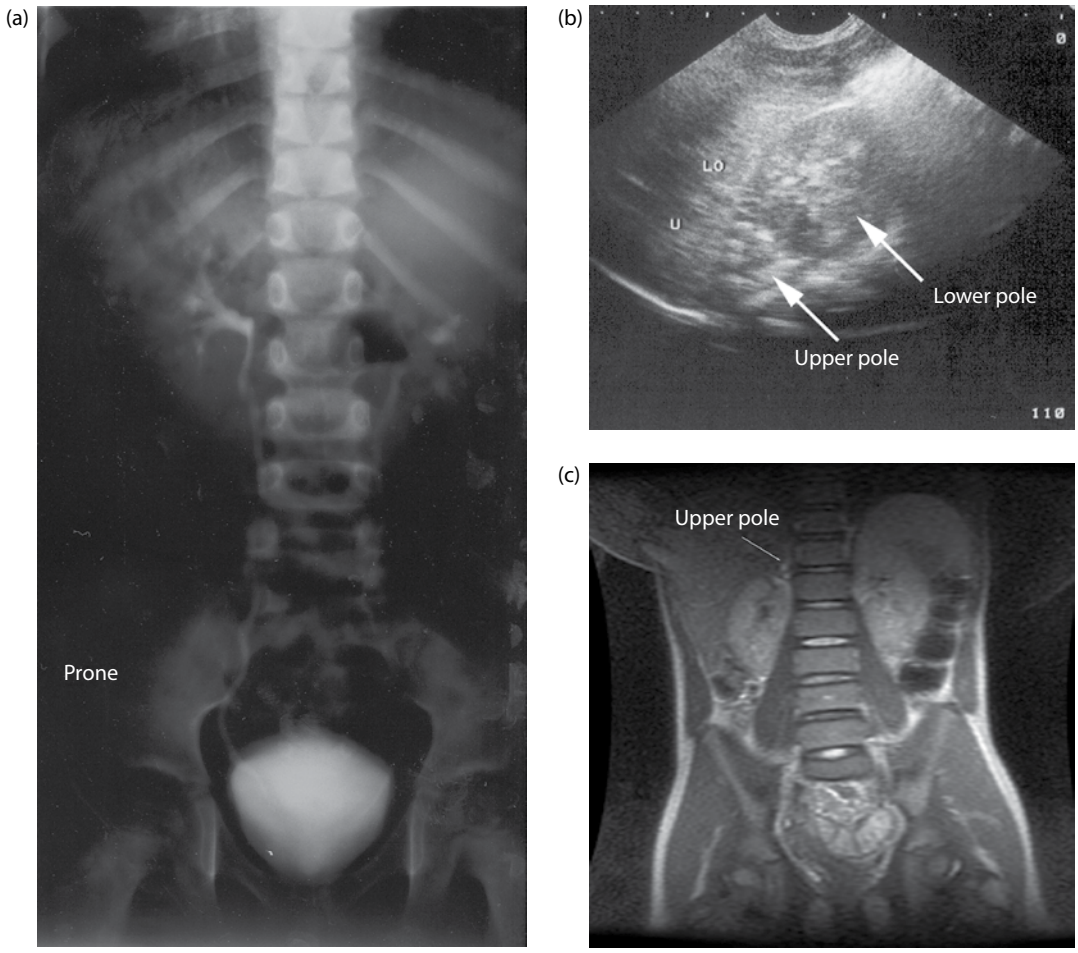

FIGURE 4.11 Duplex collecting system. A 5-year-old girl is evaluated in the office for diurnal enuresis. (a) An IVP (prone view) done previously is interpreted to be normal. Personal review of the hard copies leads to suspicion for an absent *right* upper pole. (b) IOUS is done to answer this concern and shows a bifid pattern that is consistent with renal duplication. (c) The IOUS finding prompted an MRI study, which showed renal duplication and an ectopic ureter. An ipsilateral ureteroureterostomy was performed and the enuresis resolved. This case exemplifies the use of IOUS to evaluate common outpatient pediatric urologic complaints, including enuresis. By performing an IOUS at the time of the visit, the suspicion of a duplex collecting system was pursued and led quickly to a more conclusive radiographic study (MRI), which diagnosed an ectopic ureter.

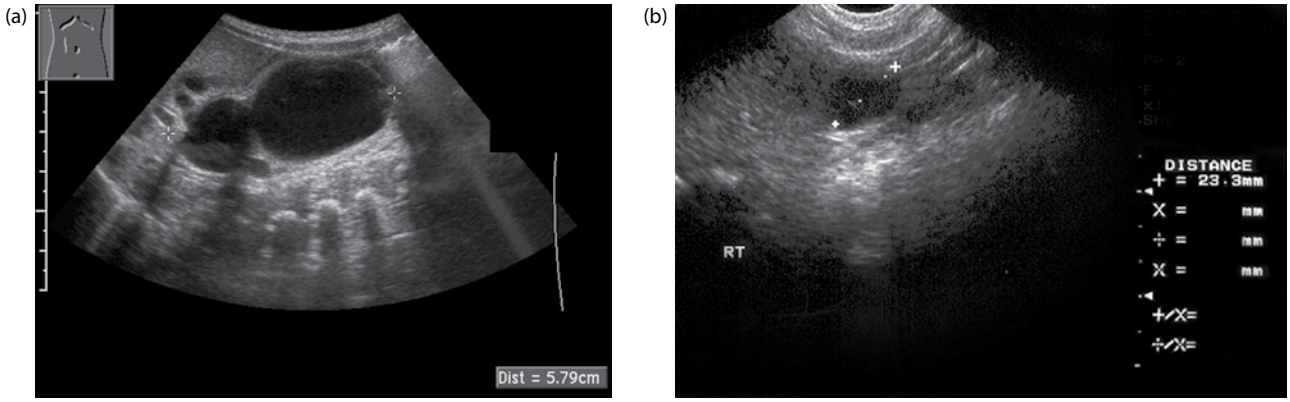

FIGURE 4.12 IOUS shows involution of an MCDK. Fetal ultrasounds of the right kidney have shown an MCDK. (a) The newborn ultrasound confirms this finding. (b) IOUS is performed 1 year later for follow-up. There is involution of the right kidney, thereby confirming the diagnosis of an MCDK.

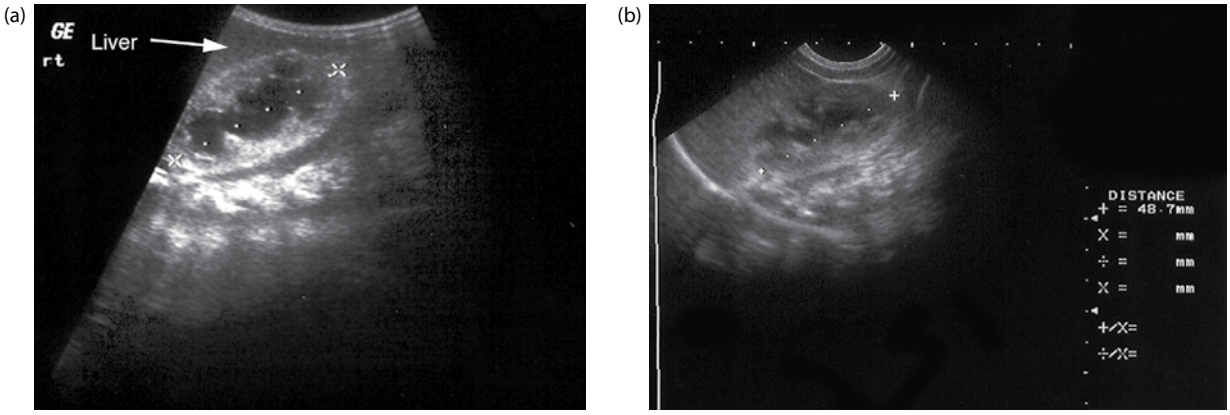

FIGURE 4.13 IOUS to follow up an echogenic, hydronephrotic kidney. (a) This neonatal boy has a renal parenchyma that is more echogenic than the liver. There is SFU Grade 3 hydronephrosis. The contralateral kidney is an MCDK (not shown). Furthermore, his older sister showed bilateral UPJO with renal hypoplasia. (b) IOUS at 3 months' follow-up shows the right kidney is echoechoic with the liver and there is less hydronephrosis (SFU Grade 2 hydronephrosis). Further management includes continuation of IOUS to survey hydronephrosis.

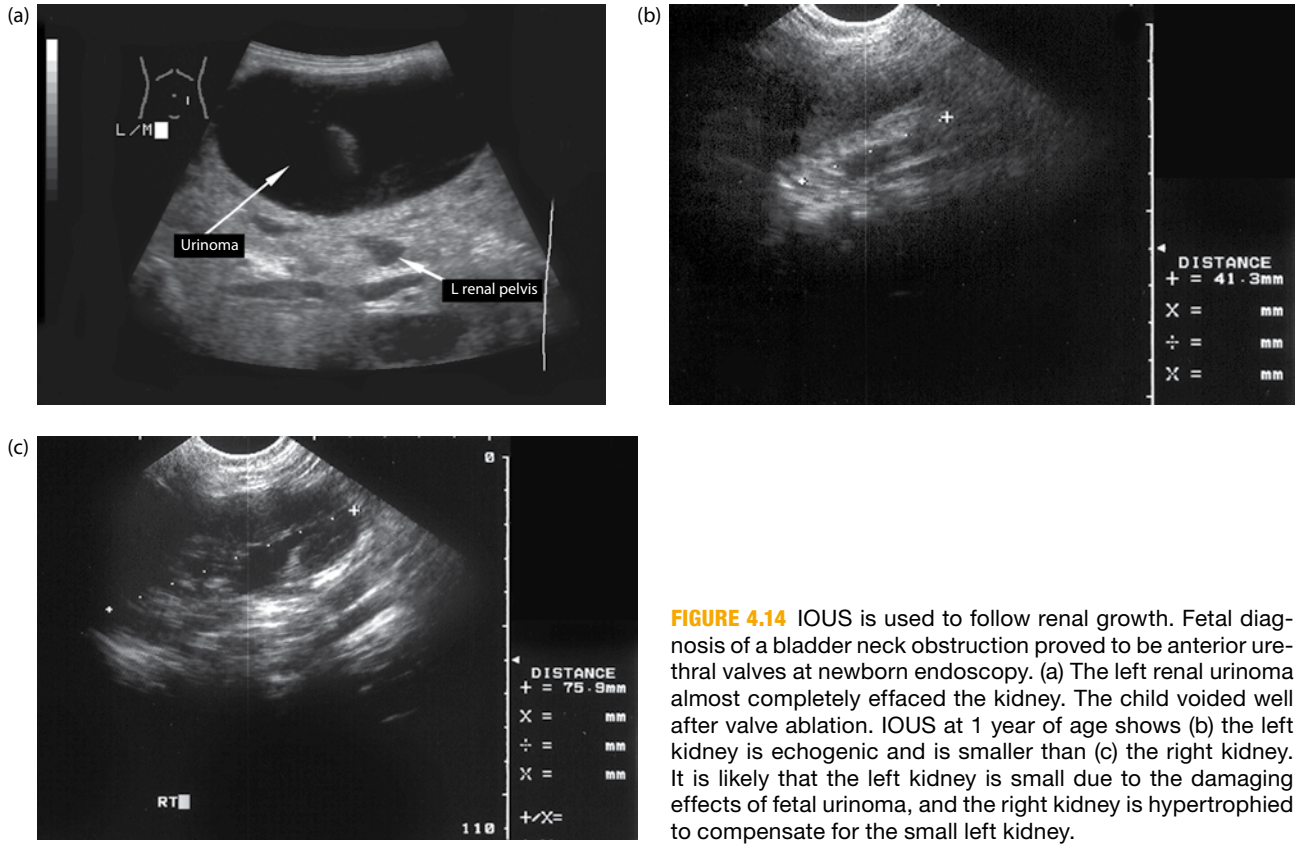

FIGURE 4.14 IOUS is used to follow renal growth. Fetal diagnosis of a bladder neck obstruction proved to be anterior urethral valves at newborn endoscopy. (a) The left renal urinoma almost completely effaced the kidney. The child voided well after valve ablation. IOUS at 1 year of age shows (b) the left kidney is echogenic and is smaller than (c) the right kidney. It is likely that the left kidney is small due to the damaging effects of fetal urinoma, and the right kidney is hypertrophied to compensate for the small left kidney.

and obstruction at the UV junction, any one of which might be detected as new or worse hydronephrosis on IOUS.

Case 12 (see Figure 4.16).

URETERS

In addition to visualizing the kidneys, IOUS may be used to image the ureters. Normal ureters are not dilated and thus are not imaged. However, dilated ureters are readily identified. Ureteral dilation is also graded according to the SFU classification system (Table 4.2).[4] Dilated ureters may accompany hydronephrosis. When ureteral dilation is present without hydronephrosis, the differential diagnosis includes VUR and primary megaureter (nonobstructive and nonrefluxing). When ureteral dilation is present with hydronephrosis, the diagnosis of a ureterovesical junction (UVJ) obstruction should be considered. By combining the SFU scores of hydronephrosis (HN) with hydroureter (HU), a SFU HUN score is calculated (SFU HN + SFU HU = SFU HUN score). We use the SFU

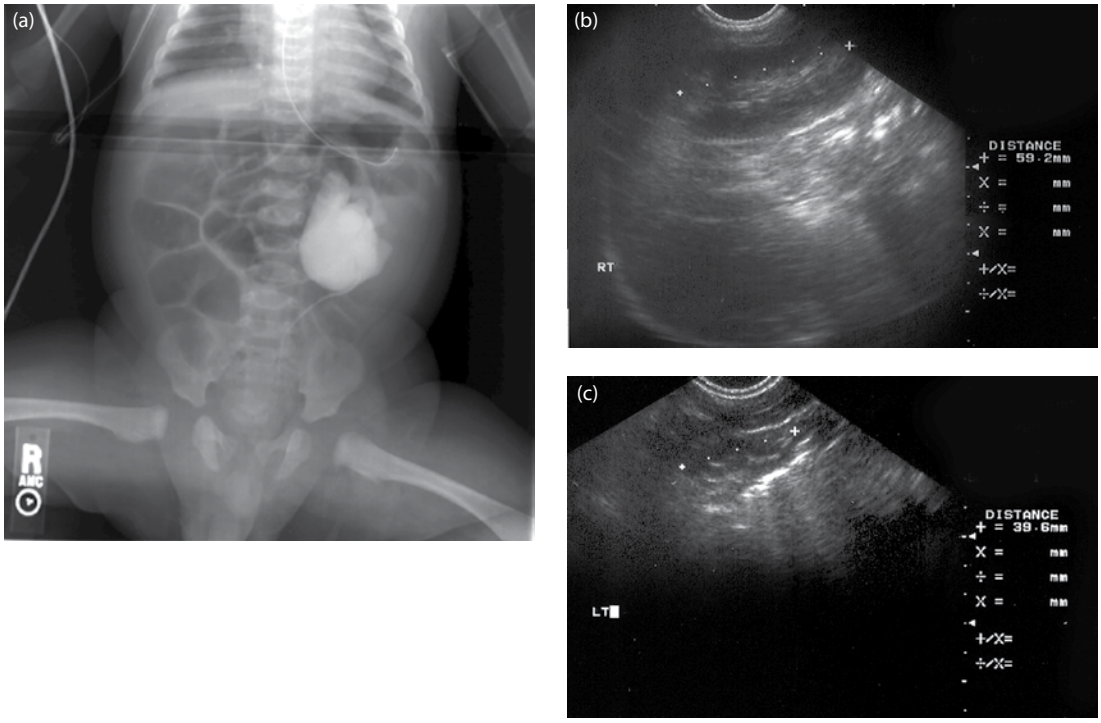

FIGURE 4.15 (a) Pyeloplasty was done for UPJO. (b) By 1 year postop, the IOUS reveals a normal right kidney and only SFU Grade 2 hydronephrosis on the left (c).

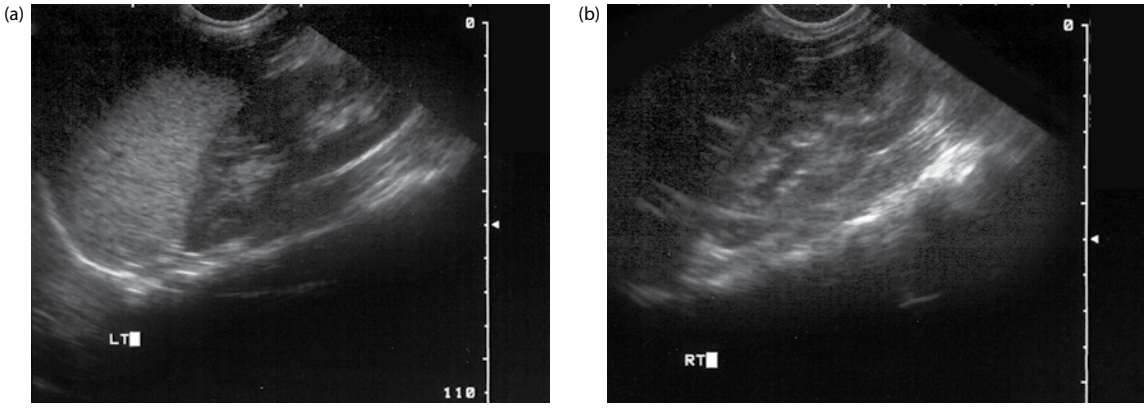

FIGURE 4.16 A 6-year-old girl with breakthrough febrile UTIs and VUR underwent bilateral detrusorrhaphy. (a and b) Two weeks postoperatively, IOUS shows normal kidneys without hydronephrosis and the bladder is empty postvoid (not shown).

TABLE 4.2 Grading of ureteral dilation

Grade 1	Less than 7 mm
Grade 2	7–10 mm
Grade 3	Greater than 10 mm

Source: Chen JJ et al. *J Urol* 2002;168:2149.

HUN score to help predict the presence or absence of obstruction, with a score of 5 or greater predictive of obstruction.[4]

Case 13: Nonobstructive, nonrefluxing primary megaureter (see Figure 4.17).

BLADDER

IOUS can be used to assess megacystis and completeness of bladder emptying, and for follow-up after endoscopic ureterocele incision.

Normal Bladder

The normal bladder, which is best assessed when partially filled or full, is smooth- walled and symmetrical and filled with echolucent urine without any other internal echoes. Urine within a neonate's bladder, however, may be echogenic, which has been attributed to the elevated levels of the Tamm–Horsfall protein. The normal capacity of the bladder may be estimated based on the age of the patient

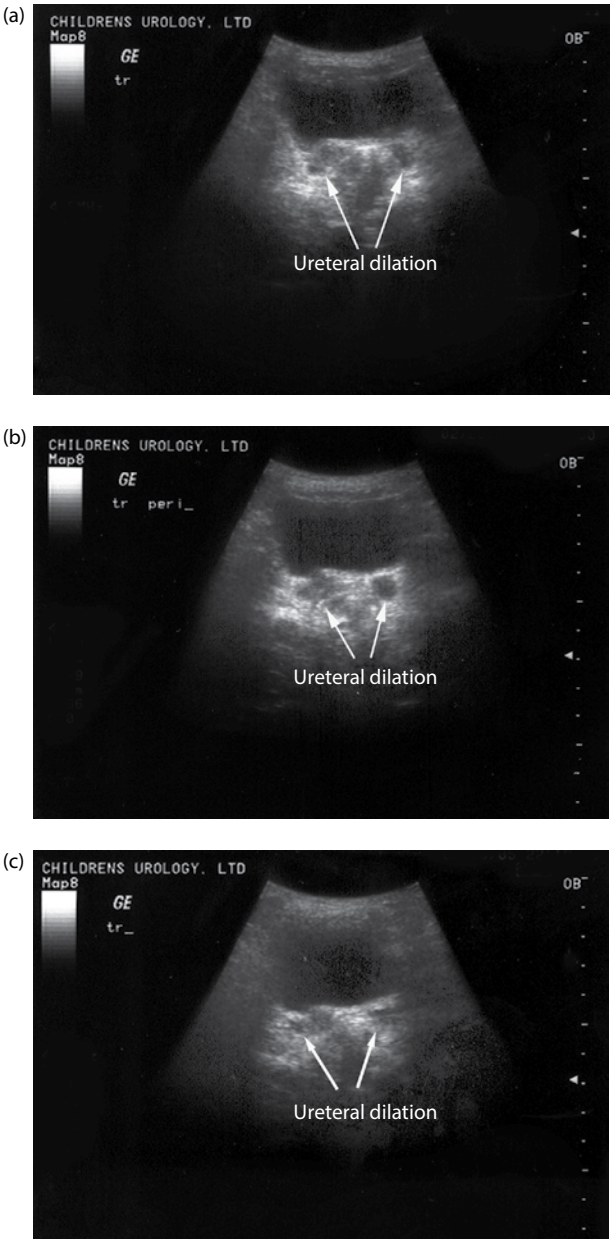

FIGURE 4.17 At 1-year follow-up for fetal SERP, IOUS shows SFU Grade 2 hydronephrosis of the kidneys (not shown). (a–c) IOUS shows that the ureter diameter fluctuates over a 30-second interval without change in bladder appearance. This represents ureteral peristalsis. These findings are consistent with nonobstructed, nonrefluxing megaureters. IOUS continues a longitudinal follow-up.

by the formula Bladder volume (oz.) = Age (years) + 2.[19] Sonographic measurement of bladder volume is obtained by measuring the transverse, longitudinal, and anteroposterior dimensions and employing the formula Bladder volume (mL) = Length (cm) × Width (cm) × Height (cm) × 0.52. IOUS may be used to measure the detrusor thickness while evaluating children with voiding dysfunction. Although the thickness of the detrusor appears distinct in the sonographic examination of the bladder, the normal thickness of the bladder wall is dependent on the extent of bladder fullness. Normative values have been described; however, no consensus has been reached.[20–23] IOUS, though, continues to be useful in following the course of bladder treatments.

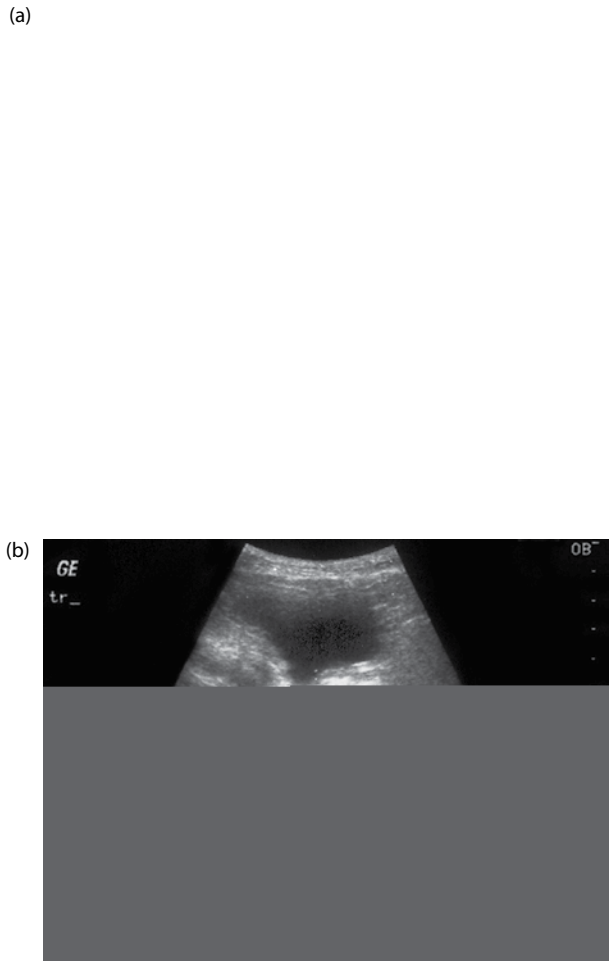

FIGURE 4.18 IOUS diagnoses megacystis or thickened detrusor. This newborn experienced a cerebral hemorrhage and acquired a neurogenic bladder. The voiding cystourethrogram showed an enlarged bladder and bilateral VUR. Intermittent bladder catheterization was instituted along with medical therapy for the cerebral hemorrhage. Oral urecholine was begun as catheterization was tapered. (a) After hospital discharge, IOUS shows a thickened detrusor. (b) After 6 months, the detrusor thickness resolved, and the diaper pattern confirmed good bladder emptying. In this case, the combination treatment with Clean Intermittent Catheterization (CIC) to ensure bladder emptying and oral urecholine to encourage bladder contraction was empiric.

Case 14: IOUS diagnoses megacystis or thickened detrussor (see Figure 4.18).

Ureterocele

Ureteroceles are commonly detected during the evaluation of hydronephrosis. The diagnosis may be missed when other causes of hydronephrosis, such as reflux, are also present. Careful evaluation of the bladder with ultrasound remains the best imaging modality to diagnose ureteroceles. Patience during the IOUS to permit the bladder to empty as the infant voids allows imaging during various stages of bladder fullness. This is important, as varying

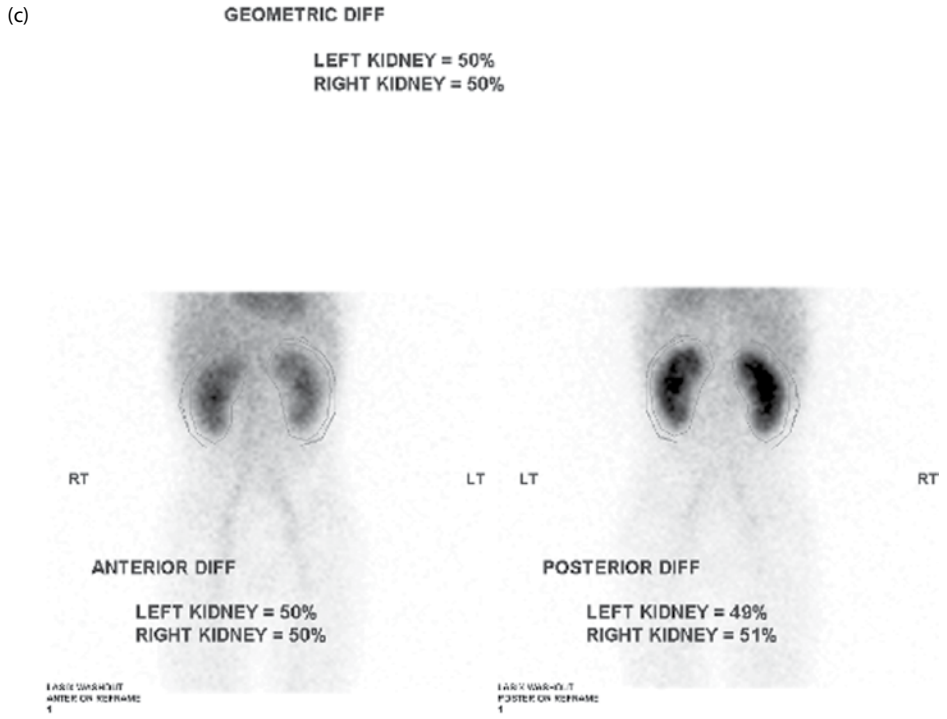

FIGURE 5.1 (Continued) (c) The geometric mean differential function was 50% in the left kidney and 50% in the right kidney.

and excludes the renal parenchyma. If hydroureter accompanies hydronephrosis, the ROI should include the ureter as well. An ROI for background subtraction is drawn lateral and inferior to the lower pole of the dilated collecting system. The drainage of the radiotracer from the pelvicalyceal system is calculated automatically and expressed as T 1/2. By increasing urinary flow after a diuretic, the dilated system may clear in the nonobstructive system. However, in the case of a mechanical obstruction, the narrowed area in the drainage route may prevent the drainage and the time–activity curve may show minimal or no evidence of downsloping. Several important points have to be made regarding assessing diuretic washout curves. First, the T 1/2 is invalid when performed on normal kidneys that have already emptied their pelves. Second, when there is poor renal function, the kidneys cannot be evaluated, as there may be poor, if any, response to the furosemide stimulation. Finally, in large hydronephrotic kidneys (pelvic volume greater than 75 mL), there will be a significant delay in emptying due to a dilution effect even though there may be no mechanical obstruction. In general, prolongation of the T 1/2 correlates with obstruction at the extremes of values. For instance, T 1/2 values of <10 minutes are accurate to exclude obstruction. Alternatively, the lack of any drainage of radiotracer (i.e., T 1/2 "infinitely long") confirms high-grade obstruction. In between, the T 1/2 becomes relatively equivocal, necessitating other clinical parameters and/or repeat assessment by diuresis renography in order to make the diagnosis of obstruction. In neonatal hydronephrosis, the natural behavior of hydronephrosis is variable and may change over time.[11] If there is no evidence of a high-grade obstruction, in uncomplicated cases, a close follow-up may be the best approach.[19]

Radionuclide Cystography

A large number of children are seen because of urinary tract infection (UTI) and vesicoureteric reflux, and radionuclide cystography (RNC) is the preferred method of follow-up because of the low radiation dose compared with conventional radiographic techniques.[19]

In direct radionuclide cystography (DRC), ^{99m}Tc-pertechnetate or sulfur colloid is instilled into the bladder via a catheter in conjunction with a saline infusion.[20] In contrast to radiographic voiding cystourethrography (VCUG), continuous recordings can be done during the bladder filling and voiding phases with no extra patient radiation (filling, voiding, and postvoiding phases) (Figure 5.2). Thus, chances of documenting reflux are enhanced. After the child voids, the residual counts can be used to quantify reflux and voiding volumes, since the concentration of isotope in the solution used to fill the bladder is known.

Indirect radionuclide cystography (IRC) following a ^{99m}Tc-DTPA or MAG3 renal scan is an alternative method to detect vesicoureteric reflux. It should be carried out once the radioisotope has completely cleared from the upper tract and accumulated in the bladder. The child is then asked to void while reflux is assessed (Figure 5.3). This method is more physiological due to the absence of bladder overfilling and has the advantages of additional information about the renal function without the need for catheterization.[21] However, the patient should be cooperative and toilet trained (>3 years old), and the radiation higher than DRC. Although this method compares favorably with micturating cystography and cystoscopy in some hands, overall, the sensitivity to detect the reflux is much lower than that of DRC.

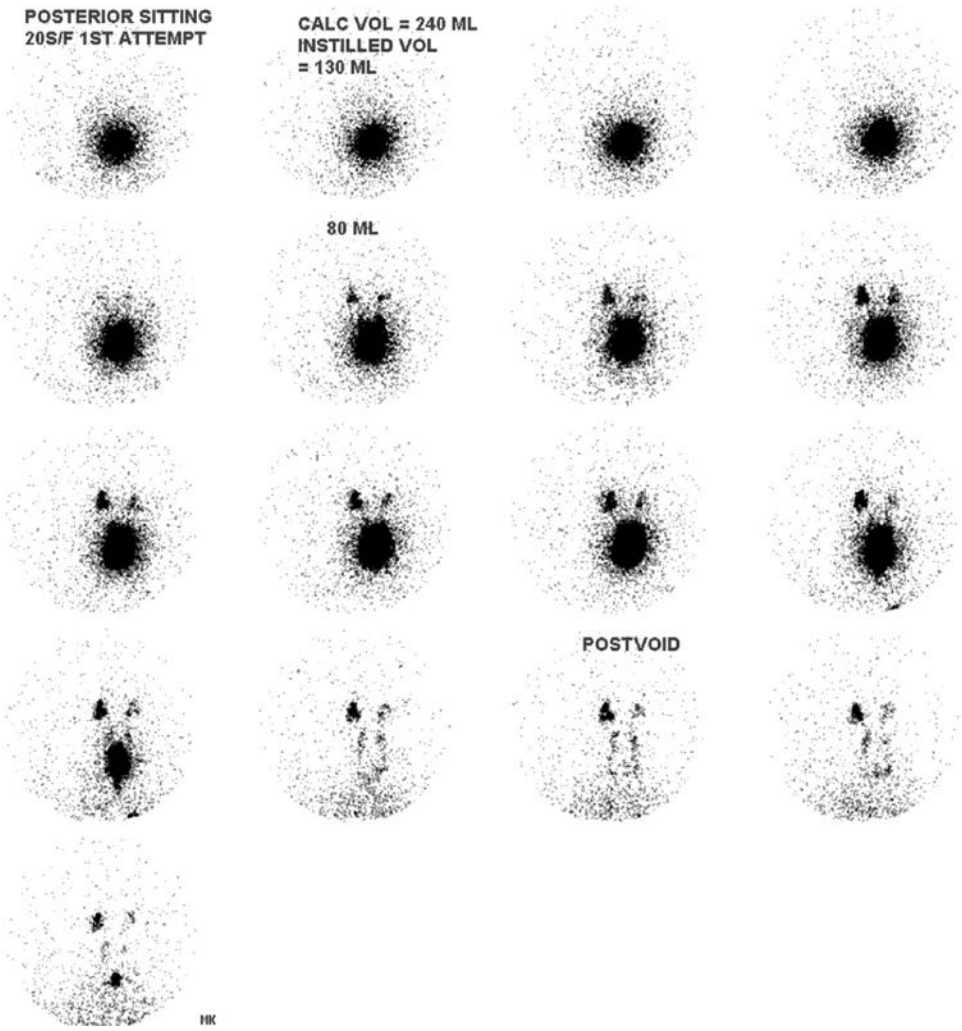

FIGURE 5.2 DRC showed that bilateral vesicoureteral reflux started at 80 mL volume during the filling phase and continued during the voiding images.

Because RNC does not provide the same anatomic detail as VCUG for the evaluation of anatomical structures, such as the PUV in a boy, a VCUG is required. The grading system of RNC and VCUG is different. With RNC, a grade 1 reflux is the visualization of the activity in the ureter (equal to grade 1 in VCUG), a grade 2 is the activity reaching the collecting system (equal to grades 2 and 3 in VCUG), and grade 3 is a dilatation of the collecting system and ureter (equal to grades 4 and 5 in VCUG).

The amount of radiation is lower in DRC than in VCUG (1 mrad/min in DRC; at least 75 mrad in VCUG, depending on the number of films taken and the fluoroscopy time). The use of modern grid-controlled variable-rate pulsed fluoroscopy has reduced the gonadal effective radiation dose by 8-fold; however, it is still 10-fold higher than for RNC.[22,23] Moreover, intermittent reflux may be missed if continuous monitoring is not performed during the filling and voiding phases. Continuous monitoring with fluoroscopy is not acceptable because of increased radiation, while in DRC the radiation will not change. RNC is appropriate for follow-up evaluation of reflux, for screening asymptomatic siblings of a patient with reflux, and for the initial evaluation of girls unless an anatomic abnormality, such as ectopic ureter or ureterocele, is suspected. For the initial evaluation of boys, it is suggested to perform a VCUG in the first assessment to exclude an anatomical abnormality in the urethra and bladder.[23]

Renal Cortical Imaging

The radiotracer of choice for the evaluation of the renal cortex is ^{99m}Tc-DMSA. Images are obtained 2–3 hours after the administration of the radiotracer when the background activity is minimal. Mild decreased activity over the area of the pelvicalyceal system is a normal finding; however, the presence of hydronephrosis correlates with increasing photopenia. Flattening of the upper lateral region of the left kidney due to splenic impression (Figure 5.4) or indentations in the contour of the kidney due to fetal lobulation are normal. External attenuation may also mimic a cortical defect. A ^{99m}Tc-DMSA renal scan is useful to evaluate ectopic kidney and horseshoe kidney; to assess the functioning cortical tissue in a dysplastic or small kidney, the DRF, and differentiation of hypertrophic columns of Bertin versus a tumor, in acute pyelonephritis; and to detect renal scars.

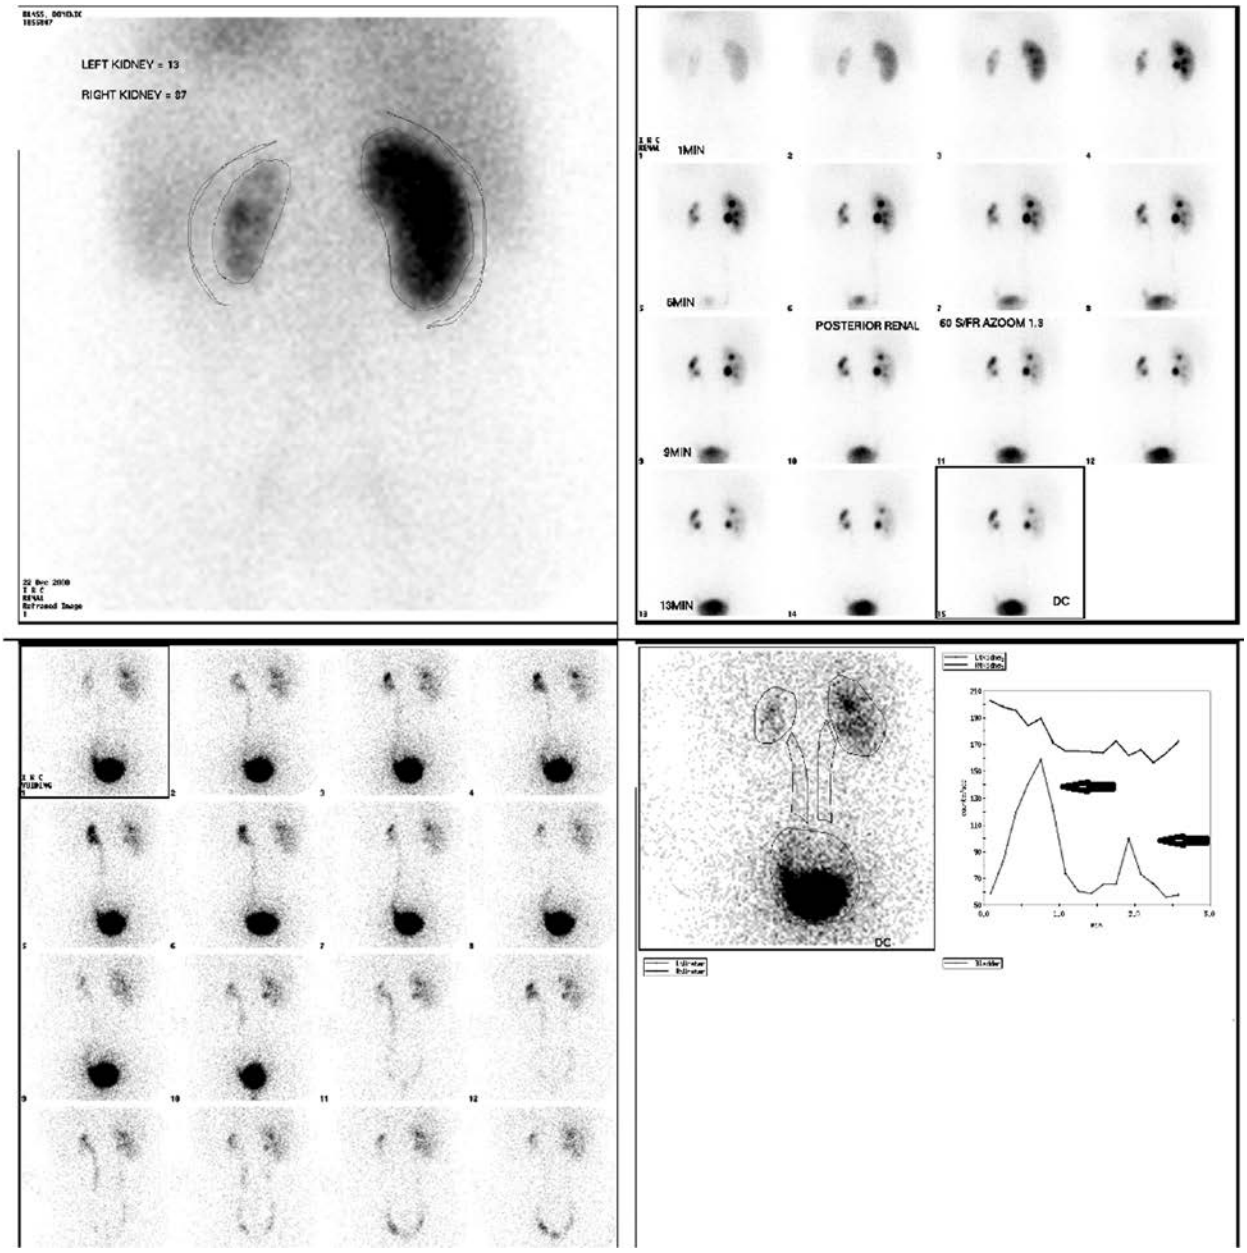

FIGURE 5.3 IRC in a 7-year-old boy shows reflux into the left kidney during the voiding phase. The study also provides further information about the function of the kidneys. The right kidney shows good uptake of the agent, followed by prompt excretion and normal drainage. The left kidney is smaller than the right kidney, with decreased differential function. The posterior differential function is 13% in the left kidney and 87% in the right kidney.

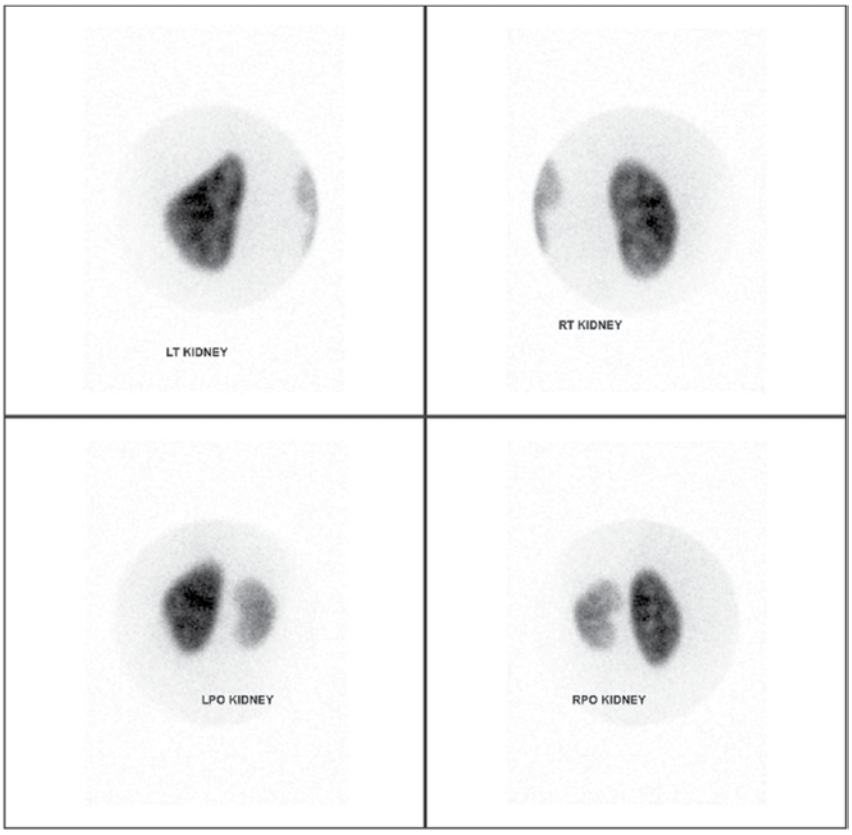
Acute Pyelonephritis

In children with UTI, radionuclide techniques are frequently performed. Direct radionuclide cystogram is the most sensitive method to detect reflux, which is present in approximately a third of children with febrile UTI. DMSA scintigraphy may be helpful in evaluating a child with febrile UTI to determine whether acute pyelonephritis is present—or has occurred.[24] Recently, some investigators suggested a so-called top-down approach with a DMSA scan as the first-line study instead of an RNC because of the relative importance of renal damage rather than reflux in these patients.[25,26]

Acute pyelonephritis appears as a single or multifocal area of decreased accumulation of ^{99m}Tc-DMSA without volume loss (Figure 5.5). Sometimes it may be revealed as a diffuse decrease in radiotracer activity. Although SPECT is better in defining the location of the lesions, it has only a marginal increase in sensitivity and a lower specificity.[27] However, it is useful for the detection of size and multiplicity of the lesions.[28]

A major concern after an episode of acute pyelonephritis is the development of scars (Figure 5.6). Ultrasound is not sensitive enough to detect renal parenchymal scars. Temiz et al. showed that, irrespective of the reflux grade,

(a)



(b)

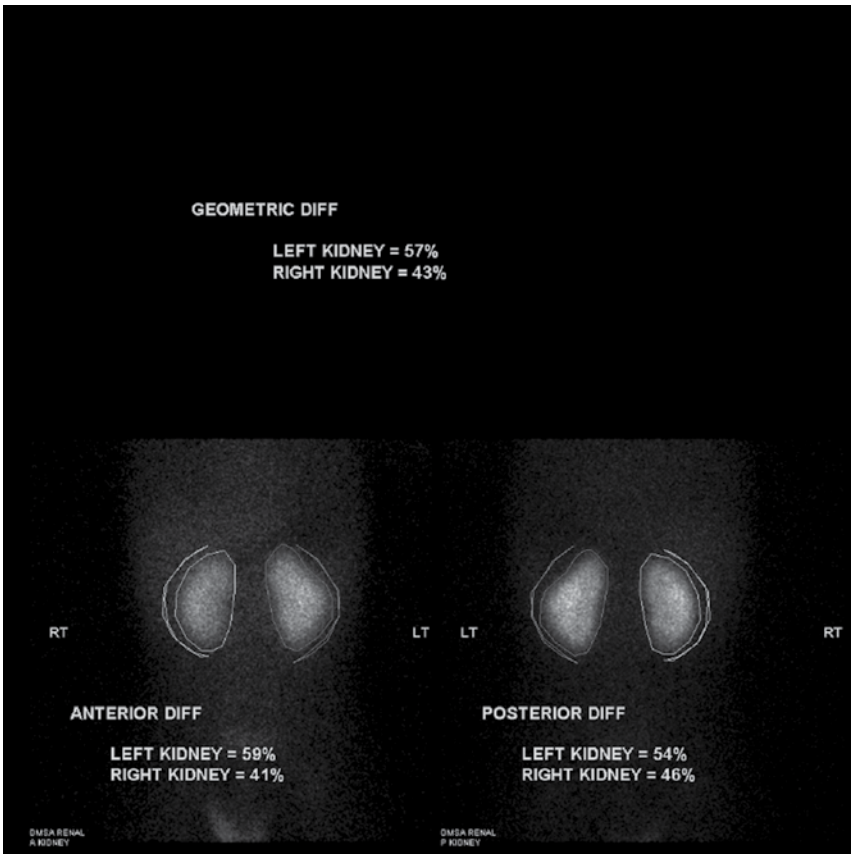


FIGURE 5.4 (a) Normal DMSA scan. Both kidneys show good uptake of the agent without any focal cortical defect or loss of volume. Note the splenic impression over the upper lateral border of the left kidney. (b) The geometric mean differential function is 57% in the left kidney and 43% in the right kidney.

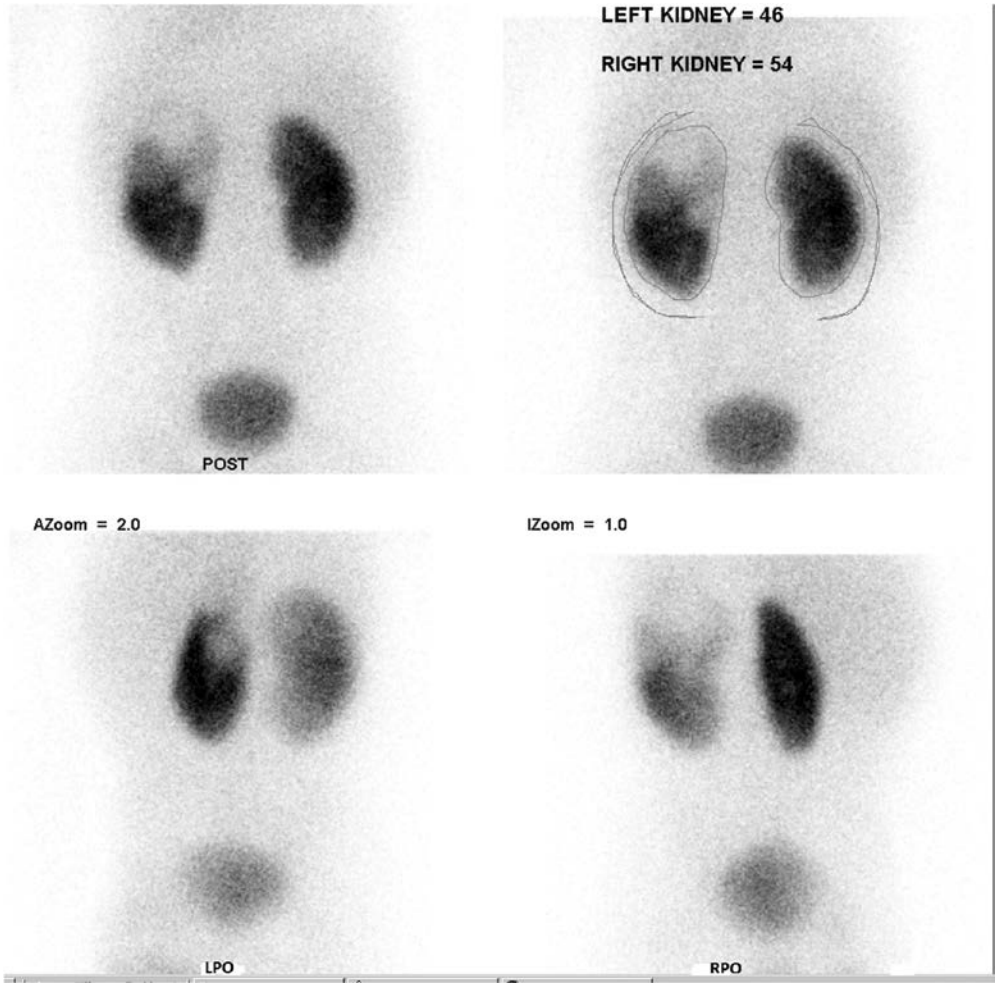

FIGURE 5.5 DMSA renal scan in a patient with febrile UTI shows decreased uptake in the upper half of the left kidney, which suggests acute pyelonephritis.

^{99m}Tc-DMSA scan detected scars in 35% of the kidneys reported to be normal on ultrasound.[29] Others have found similar low sensitivity for ultrasound to detect renal scars.[30,31]

The possibility of renal damage is increased when the patient has a high fever and septicemia in acute pyelonephritis, in atypical forms of microorganisms, when the patient fails to respond to antibiotic therapy after 48 hours, in different treatment regimens, and in repeated infections.[32,33] Decreased cortical uptake after an acute pyelonephritis may resolve during several months or may lead to a permanent scar formation. A follow-up ^{99m}Tc-DMSA study at least 6 months after the acute pyelonephritis may be useful to detect scarring.[34] With ^{99m}Tc-DMSA SPECT, not only is it easier to define whether scars are present, but also location and definition are enhanced.[28]

CONGENITAL ANOMALIES

Ectopic kidneys: Ectopic kidneys (Figure 5.7) are seen well with the nuclear scan, despite bowel gas or bony structures that sometimes obscure the ectopic kidney to intravenous pyelogram (IVP) and ultrasound. The diagnostic dilemma of a solitary kidney on IVP can be sorted out with the aid of a renal scan and ultrasound. These latter two modalities will distinguish renal ectopia from hypoplasia or agenesis.

Horseshoe kidney: The horseshoe kidney (Figure 5.8) poses a special problem. It is often difficult to decide on the IVP if there is functioning renal tissue joining the lower poles of the kidneys because this part of the kidney overlies the spine. If one employs DMSA and takes anterior images, it is possible to detect the presence or absence of functioning tissue in the isthmus; Wilms' tumor, with which a horseshoe kidney is sometimes associated, can occasionally be identified. If horseshoe kidneys are slow to drain, one can assess obstruction using a diuretic renal scan (Figure 5.9).

Duplex kidney: The radionuclide renal study is frequently used to confirm the presence of *renal duplication*, suspected on IVP or ultrasound, or may even diagnose unsuspected cases. The function of each moiety can be individually assessed as well. The upper and lower parts of the duplex kidney are quantified relative to each other,

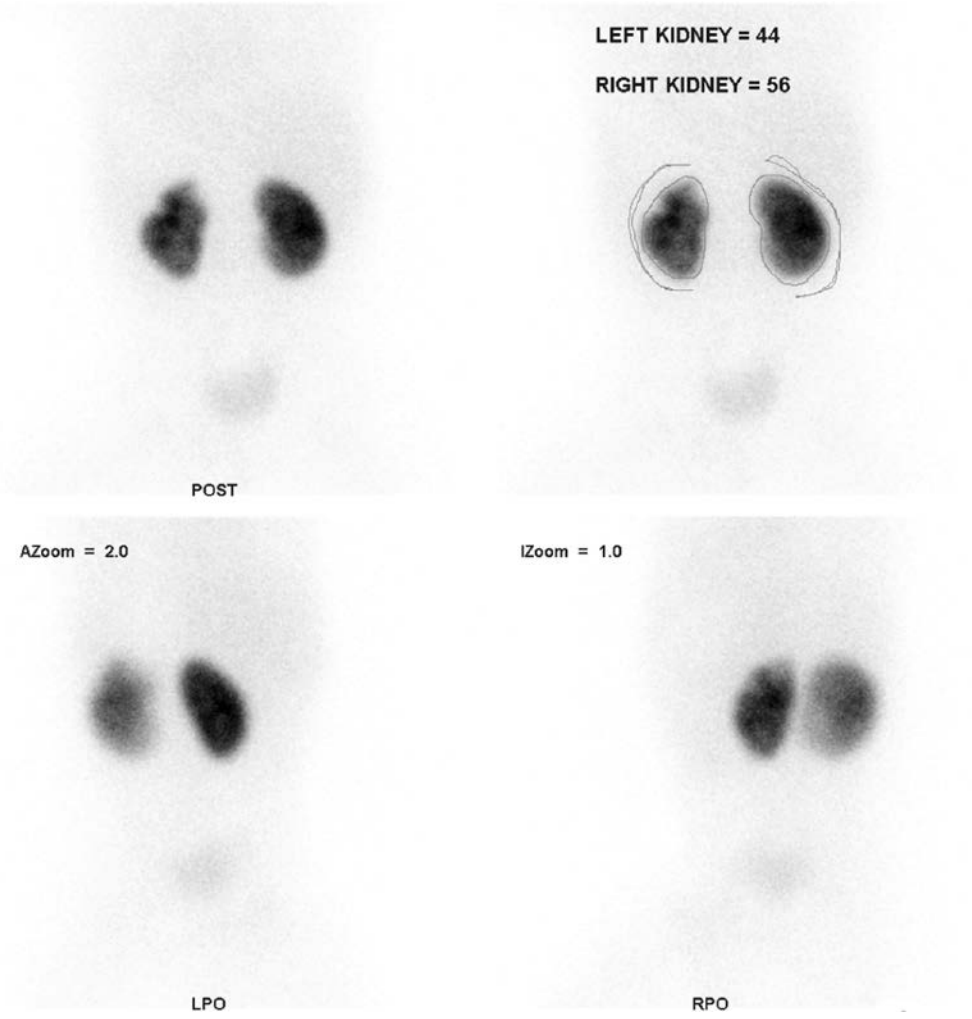

FIGURE 5.6 DMSA renal scan in a 1-year-old male with a history of pyelonephritis and bilateral vesicoureteral reflux shows two foci of cortical defects in the upper and upper lateral region of the left kidney. The posterior differential function is 44% in the left kidney.

as well as to the opposite kidney (Figure 5.10). This is important in deciding whether there is enough function to salvage an abnormal renal segment. Most commonly, the upper component functions less well than the lower one, because of obstruction from an ectopic ureter or ureterocele. Occasionally, however, the lower component of the duplex kidney may have less function, and in this situation, one has to be suspicious of reflux nephropathy of the lower collecting system or ureteropelvic junction (UPJ) obstruction.

Ureteropelvic junction obstruction: The child with UPJ obstruction is usually evaluated pre- and postoperatively for the degree of relative renal function, absolute renal function, and rate of egress of the radioactive urine from the kidneys.

A diuretic renogram permits a quantitative assessment of the effect of surgery and/or postoperative complications on the renal drainage system. However, it should be kept in mind that in children who have had repair of a UPJ obstruction or after reimplantation of the ureters as an antireflux surgical procedure, delays in drainage may persist for several months before eventual improvement.

RENAL TRANSPLANT ASSESSMENT

In children with a renal transplant, the renal scan has been used during the first 2 weeks to evaluate the effectiveness of the transplant surgery. As the renal transplantation techniques have improved significantly, the need for an immediate renal evaluation is not as important. Usually, a renal scan is performed in the first 48–72 hours if the urine output is normal and blood pressure and creatinine (Cr) are as expected. This early renal scan helps us to detect early complications after renal transplant, as well as serves as a baseline study for further comparison. At 2 weeks after the transplantation, the first GFR assessment is performed. Then on a regular basis, the GFR is measured every year. The complications and findings in renal scan are summarized in Table 5.3 (Figure 5.11).

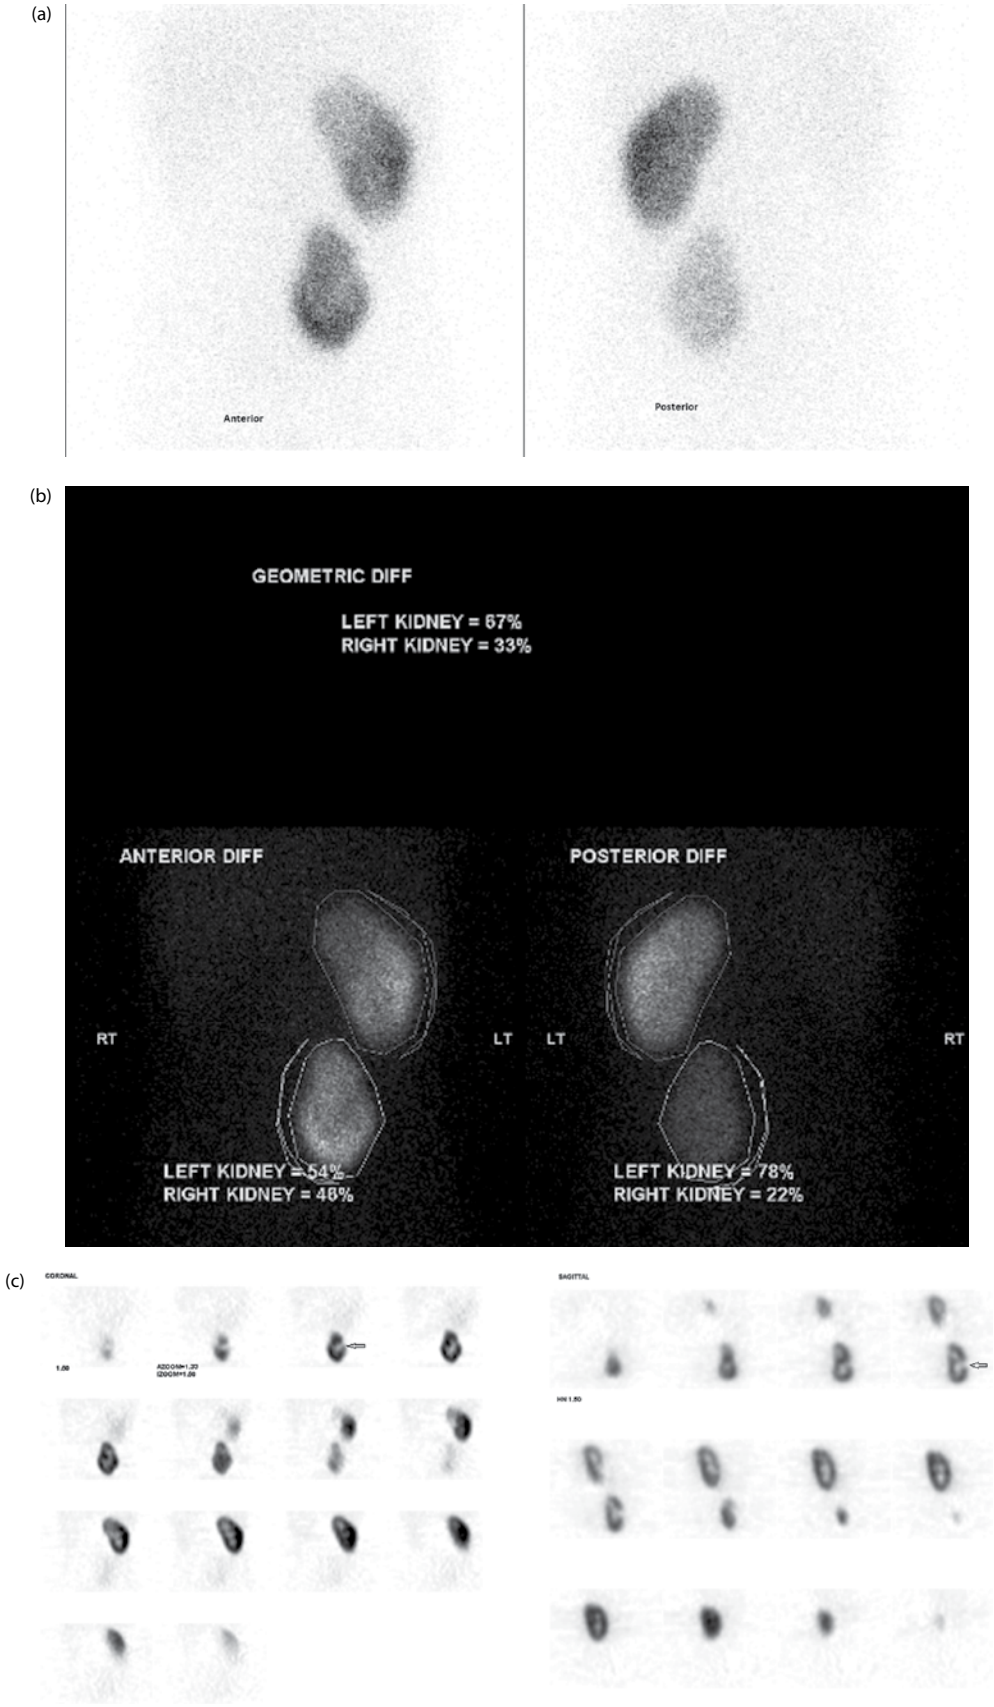

FIGURE 5.7 (a) DMSA renal scan in a patient with an ectopic pelvic kidney. (b) The geometric mean differential function is more reliable than the posterior views to assess the relative function. (c) On SPECT images, there is a focal cortical defect in the ectopic kidney (white arrow), which suggests a scar that was difficult to detect on planar views.

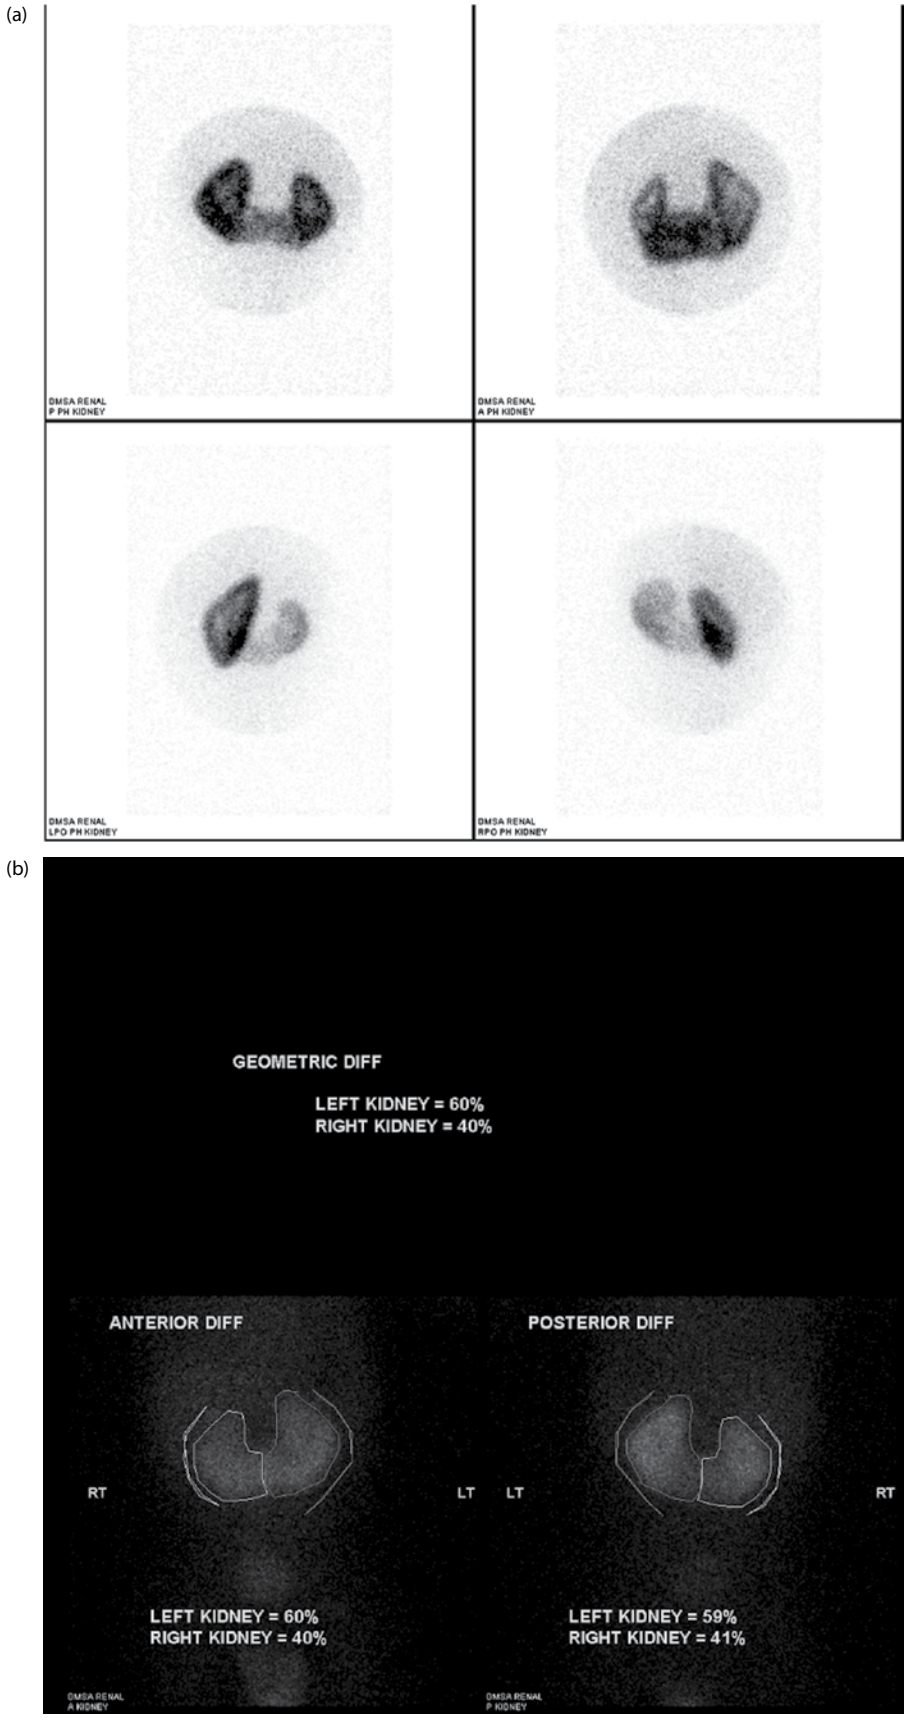

FIGURE 5.8 DMSA renal scan in a 4-year-old boy shows horseshoe kidneys. (a) The presence of fused renal tissue in the midline (isthmus) makes any selection of ROIs arbitrary. (b) In this case, the approximate contribution is 60% from the left moiety and 40% from the right.

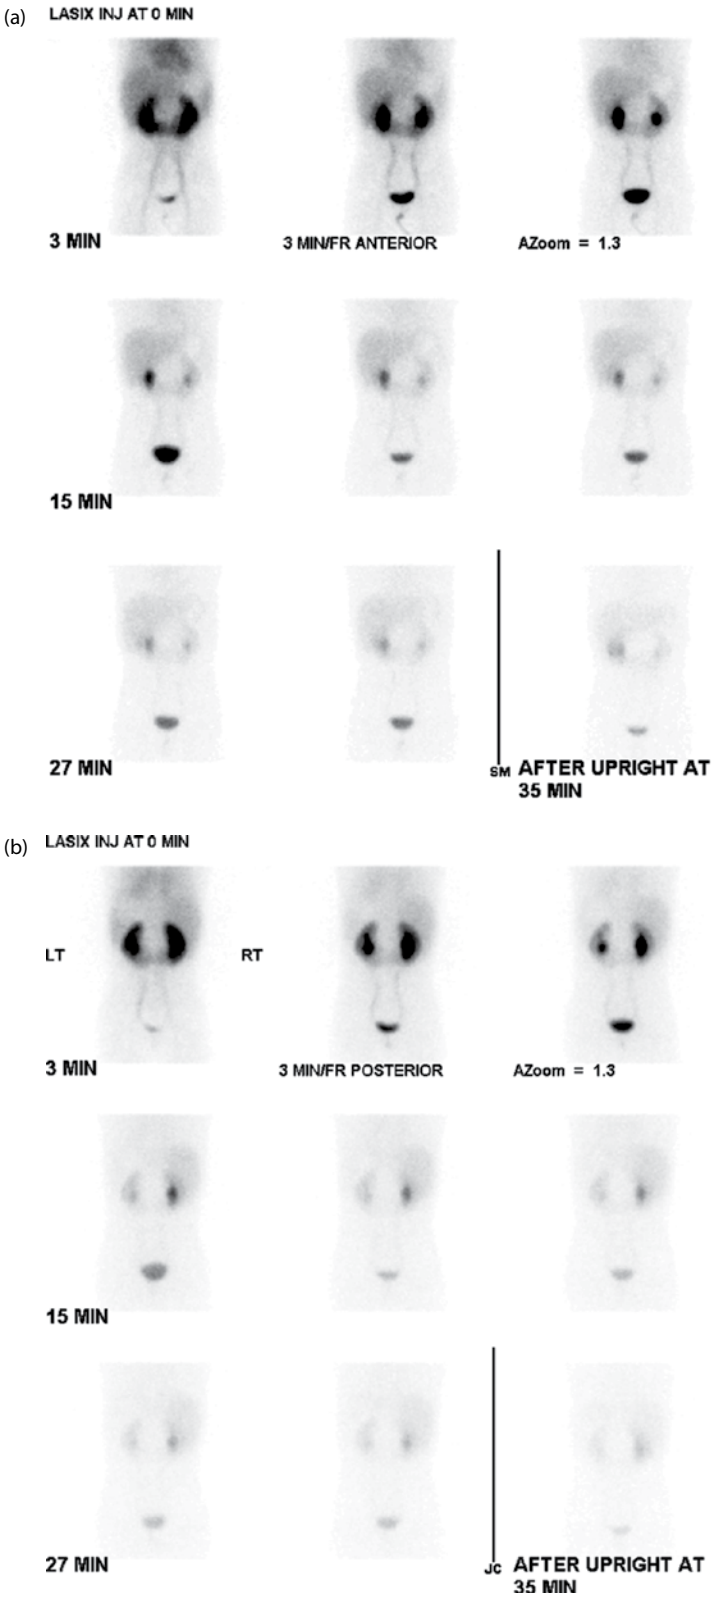

FIGURE 5.9 (a and b) Diuretic renal scan in a patient with horseshoe kidneys shows good uptake of the agent by the kidneys with prominent calyceal systems bilaterally and normal drainage without obstruction. (*Continued*)

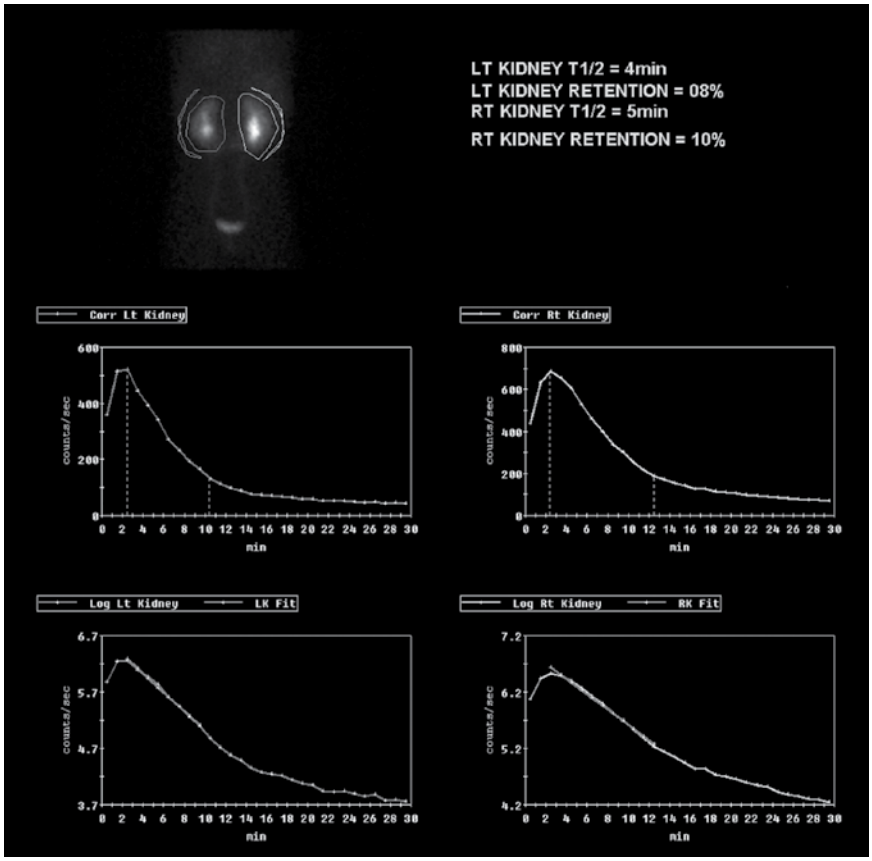
(c)



(d)

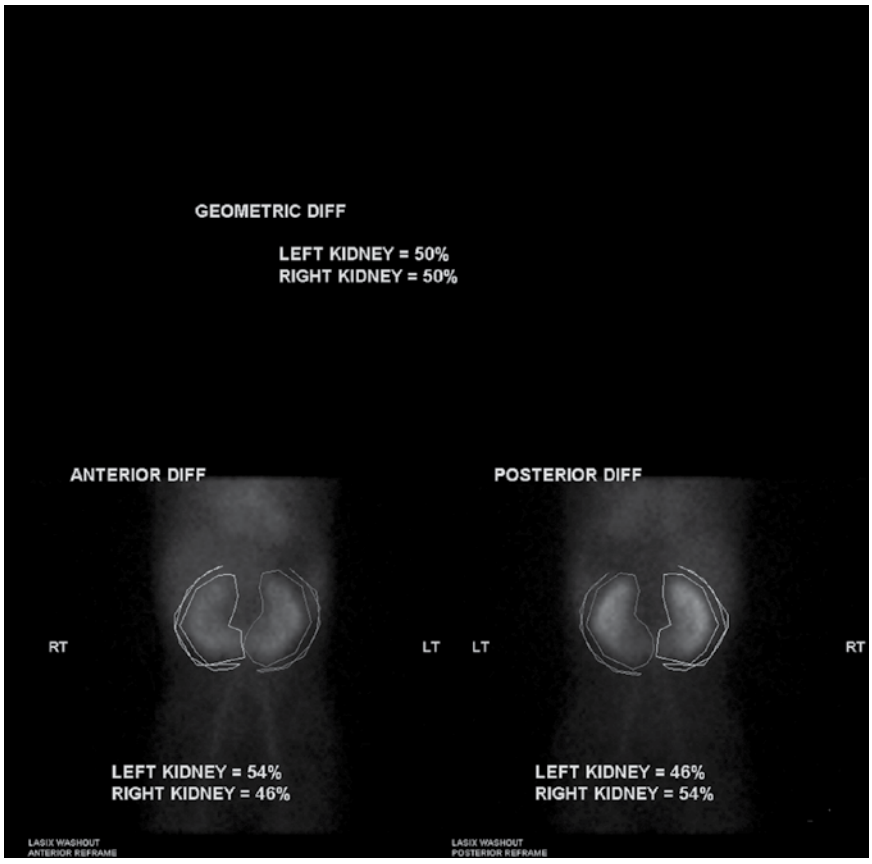


FIGURE 5.9 (Continued) (c) The semiquantitative values are within the normal range with normal renograms (exponential shape). (d) Arbitrary ROIs are drawn over the kidneys to assess the differential function.

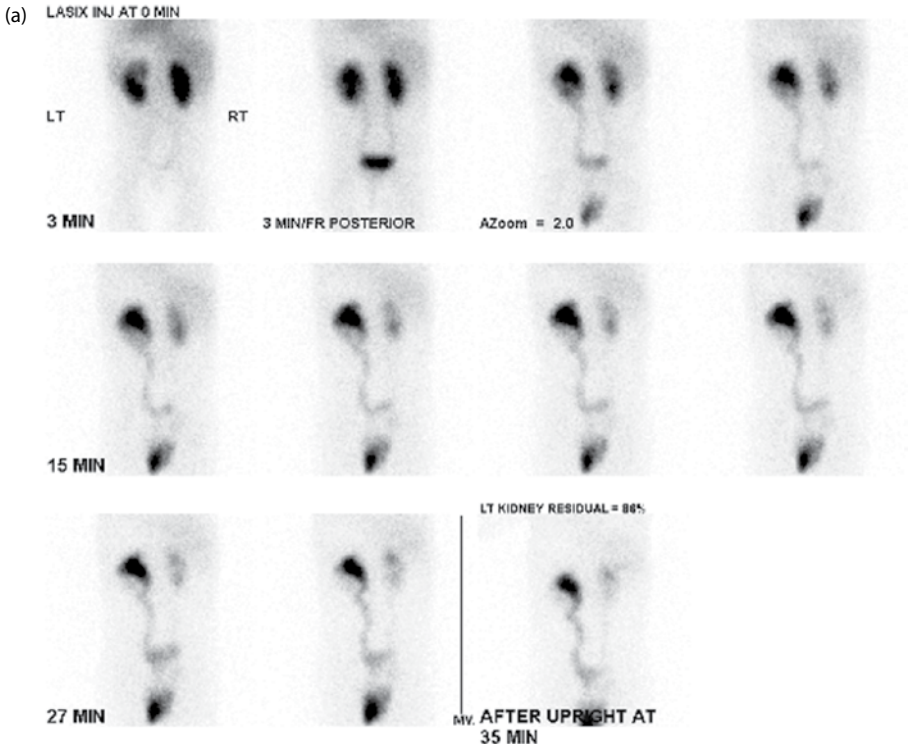

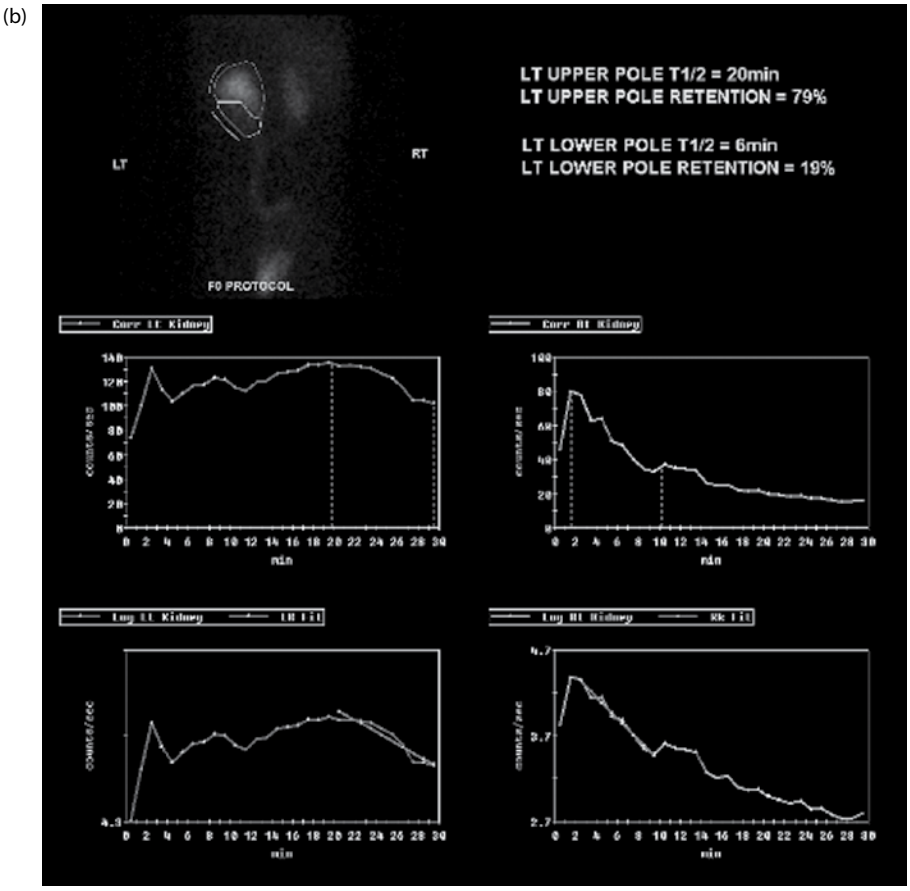

FIGURE 5.10 Diuretic renal scan in a patient with a left duplex system. (a) The lower moiety of the left kidney shows good uptake of the agent with prompt excretion and normal drainage. The upper moiety shows decreased cortical uptake and a dilated pelvicalyceal system. The left ureter is tortuous. The drainage of the pelvicalyceal system of the upper moiety is delayed, which suggests an obstruction. (b) An arbitrary ROI was drawn over the upper and lower moiety of the left kidney. T 1/2 is 20 minutes for the upper moiety and 6 minutes for the lower moiety. (*Continued*)

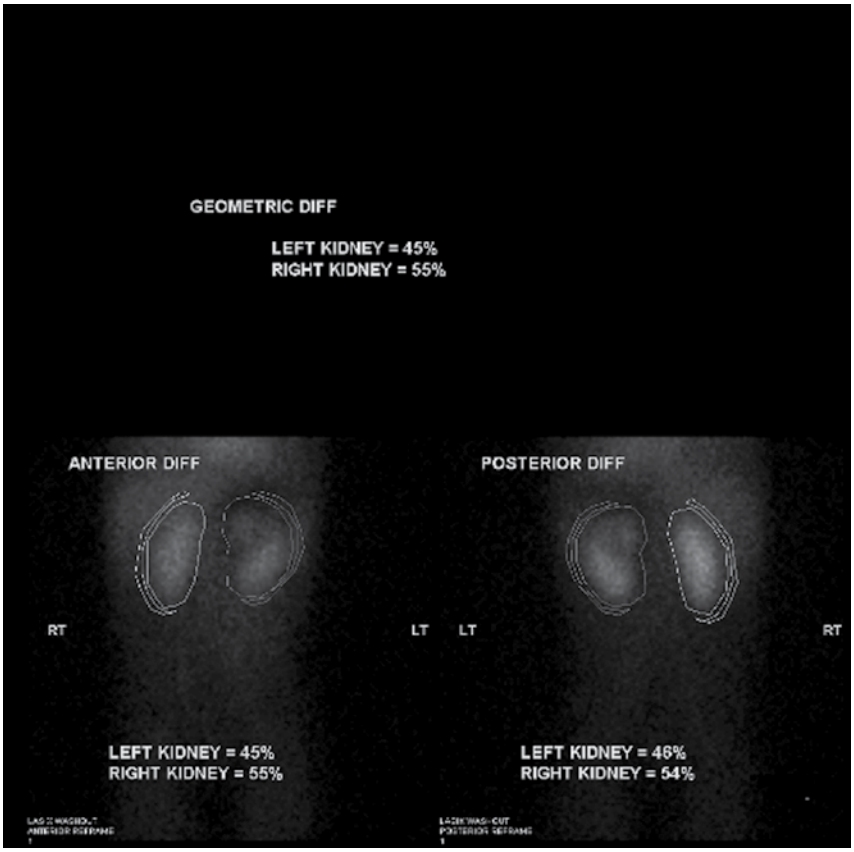
(c)



(d)

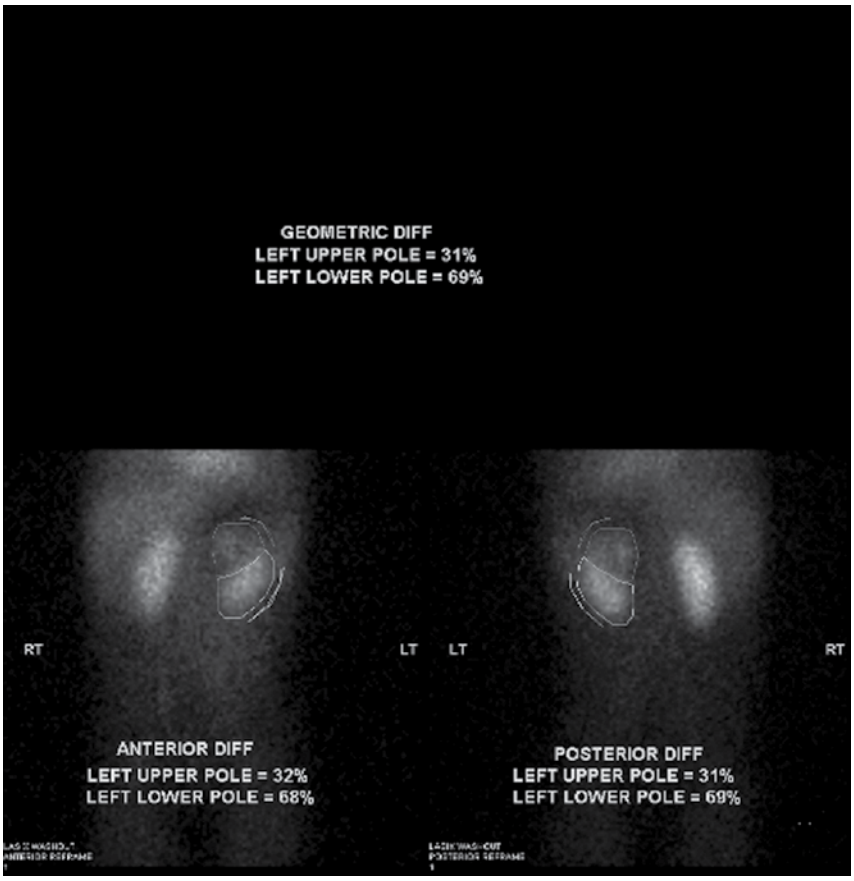


FIGURE 5.10 (Continued) (c) The geometric mean differential function is 45% in the left kidney and 55% in the right kidney. (d) The differential cortical function is 31% in the upper portion and 69% in the lower portion.

TABLE 5.3 Complications of renal transplants

Complications	Nuclear medicine procedure	Findings
Vascular		
Renal artery occlusion	Tc-MAG3 renography	A photon-deficient area at the region of the transplanted kidney
Renal artery stenosis	ACEI renography	Depending on the severity of stenosis, revealed as decreased flow and cortical uptake exaggerated after ACEI
Renal vein thrombosis	Tc-MAG3 renography	Severely decreased or no flow and cortical uptake[a]
Renal		
Acute rejection	Tc-MAG3 renography	Decreased perfusion and cortical uptake with mild retention[b]
Chronic rejection	Tc-MAG3 + ERPF study	Gradual decreased function of the kidney (gradual decrease of ERPF or GFR)
Acute tubular necrosis (vasomotor nephropathy)	Tc-DTPA + GFR study Tc-MAG3 renography	Normal flow but increased cortical retention[c]
Cyclosporine A nephrotoxicity	Tc-MAG3 renography	Similar to ATN, sometimes reduced flow to a lesser degree
Infarcts	Tc-DMSA	Focal cortical defect with volume loss
Others		
Urinary leakage (urinoma)	Tc-MAG3 renography	A progressive abnormal radiotracer accumulation outside of the urinary tract
Postrenal obstruction (calculus, blood clot, stricture, etc.)	Tc-DTPA renography Diuretic renography	Pattern of upsloping or minimal downsloping after lasix injection with increased T 1/2
Vesicoureteral reflux	DRC or IRC	Reflux of the radiotracer into the transplanted ureter and kidney

[a] Due to the lack of collaterals in a transplanted kidney, the effect of renal vein thrombosis on a transplanted kidney is more severe than that on a native kidney.
[b] Acute rejection (AR) may be superimposed on a vascular nephropathy, showing a mixed appearance of AR and Acute Tubular Necrosis (ATN) on MAG3 renography.
[c] A baseline scan is very useful to differentiate between ATN and AR; in AR, usually the baseline study is normal.

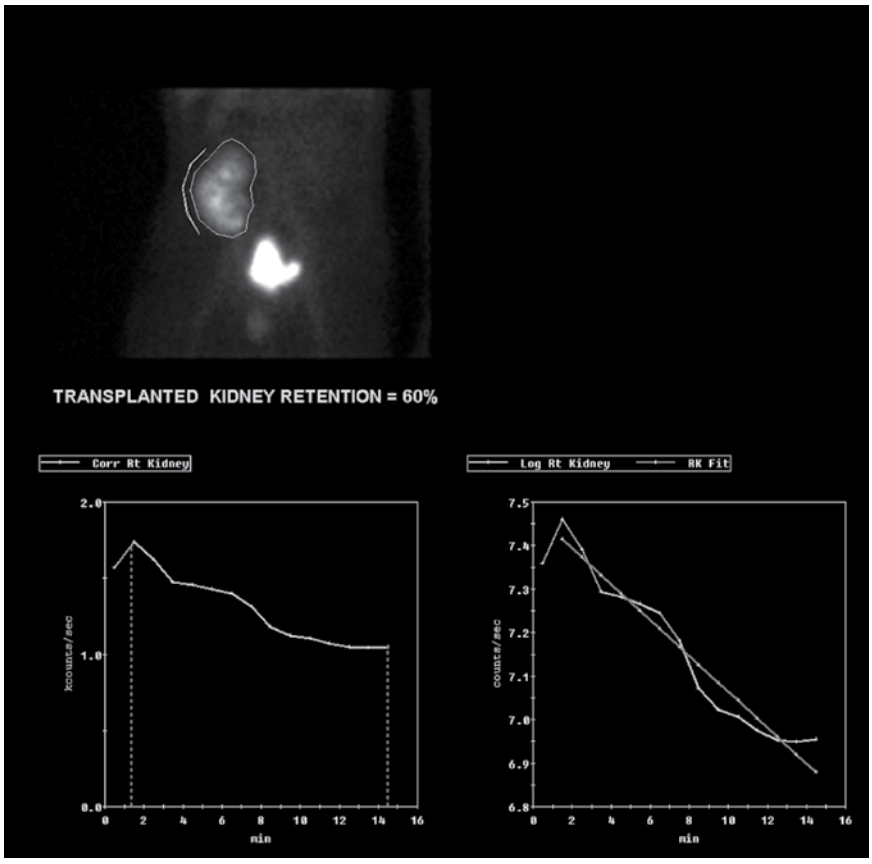

FIGURE 5.11 (Continued) Cortical uptake, excretion, and drainage of the transplanted kidney (a2) with a normal renogram (a3). (*Continued*)

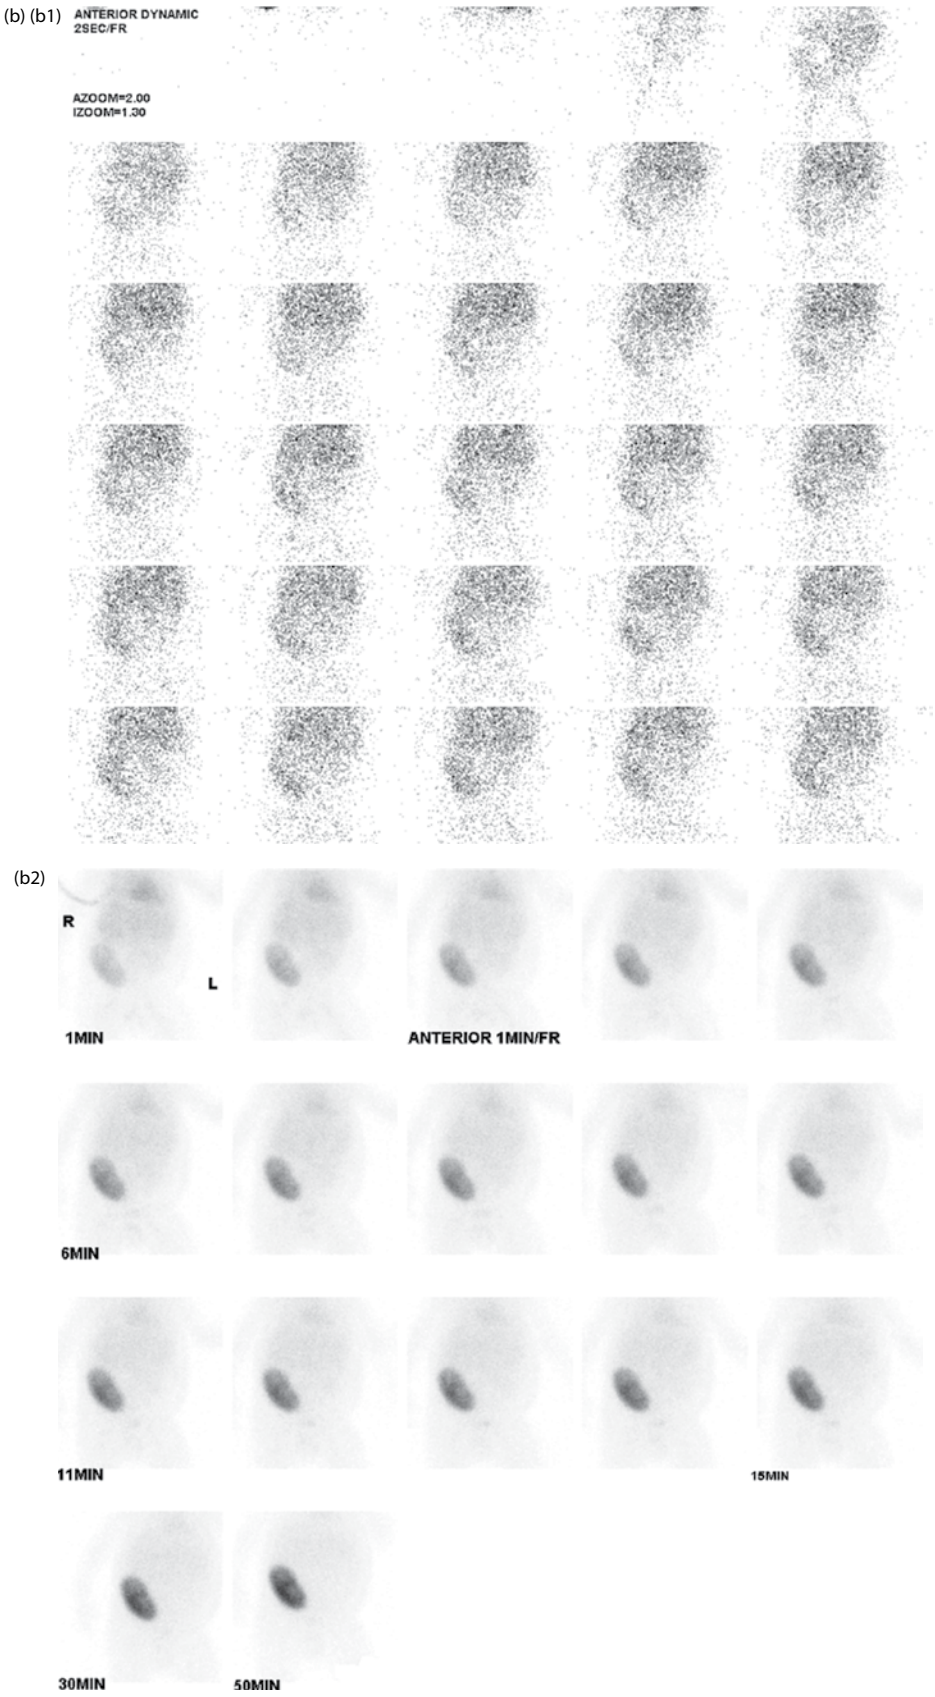

FIGURE 5.11 (Continued) (b) Renal scan for the evaluation of a transplanted kidney on day 1 after transplantation in another patient. The aortic peak activity is decreased and delayed, which suggests a poor bolus of administered radiotracer. In view of a poor bolus, the perfusion to the transplanted kidney appears to be normal or slightly decreased (b1). (*Continued*)

(b3)

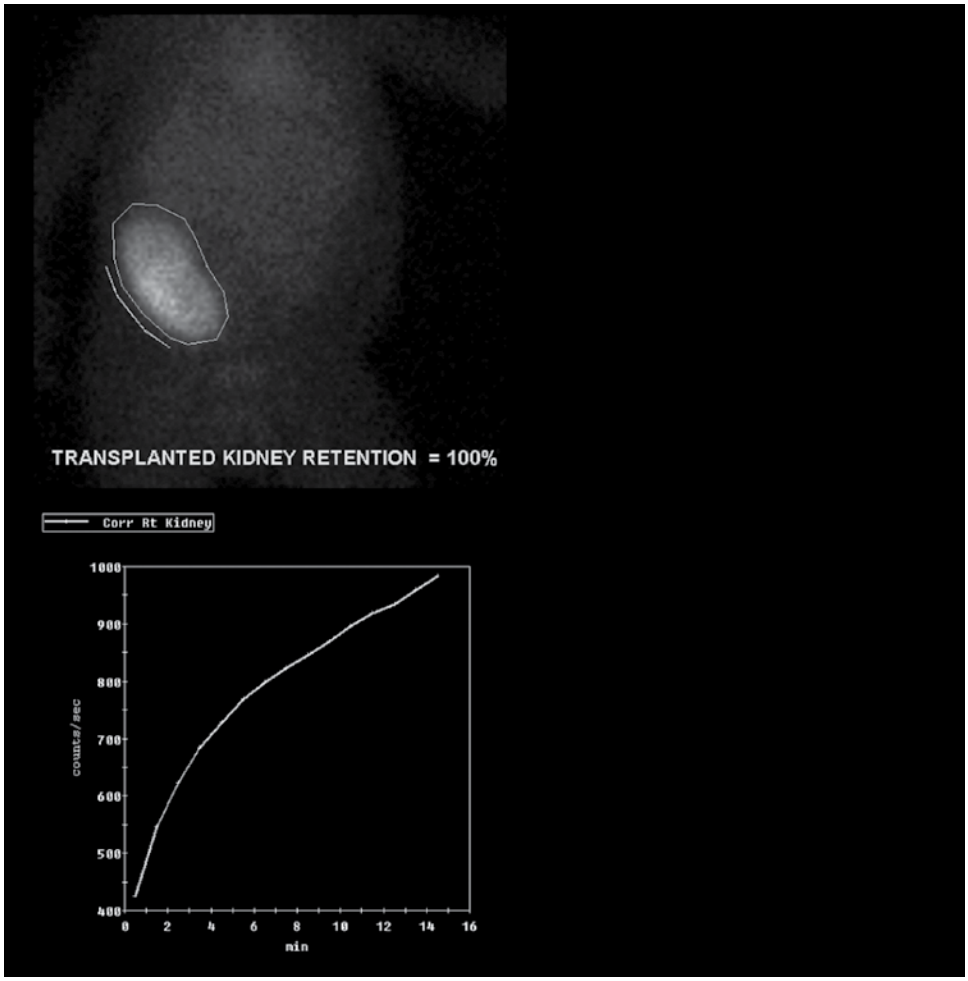

FIGURE 5.11 (Continued) However, there is considerable cortical retention in the transplanted kidney, which suggests acute tubular necrosis (b2 and b3).

KIDNEY TRAUMA

^{99m}Tc-MAG3 renography is a useful method to assess renal function as well as the renal anatomy after either a blunt or a penetrating trauma in a stable patient. Although ultrasound, CT, and IVPs are the common methods for evaluating trauma, sometimes it is important to know the degree of functional impairment. The sensitivity of SPECT ^{99m}Tc-DMSA imaging for renal trauma is very high; it compares favorably to CT and is superior to ultrasound and IVP. Frequently, a band or a section of the kidney with depressed renal function due to fracture is seen (Figure 5.12). Sometimes, a focus of decreased activity may be noted due to a hematoma, which may subsequently subside on follow-up studies.

RENAL ARTERY STENOSIS

Renovascular hypertension constitutes approximately 10% of the secondary hypertension in children. Renal artery stenosis, usually due to fibromascular dysplasia, is the most common cause of renovascular hypertension in pediatrics. When there is a significant artery stenosis, the renin–angiotensin system will be activated in order to maintain the filtration pressure and GFR of the affected kidney. By using the angiotensin-converting enzyme inhibitors (ACEIs), the GFR of the affected kidney will decrease. ACE inhibition renography with Tc-MAG3 or Tc-DTPA is a noninvasive method to evaluate the functioning effects of a stenosis. After using an ACEI, the function of the affected kidney will decrease compared with the baseline study.

The patient should be well hydrated for both pre- and post-ACEI studies. It is recommended to insert an intravenous line for high-risk patients and for the postenalapril study (for instant fluid infusion in the case of hypotension). The patient should be monitored every 15 minutes after the administration of ACEI. Before the study, the patient should discontinue enalapril for 5 days, captopril for 3 days, and diuretics and calcium channel blockers for a few days. It is also suggested to discontinue angiotensin II receptor blockers. However, if the risk of severe hypertension is high, the study may be done without discontinuation of ACEIs, although the sensitivity will decrease.[35] For postcaptopril study, the patient should not eat a solid meal for 4 hours before the study, to avoid any interference with the absorption of captopril.

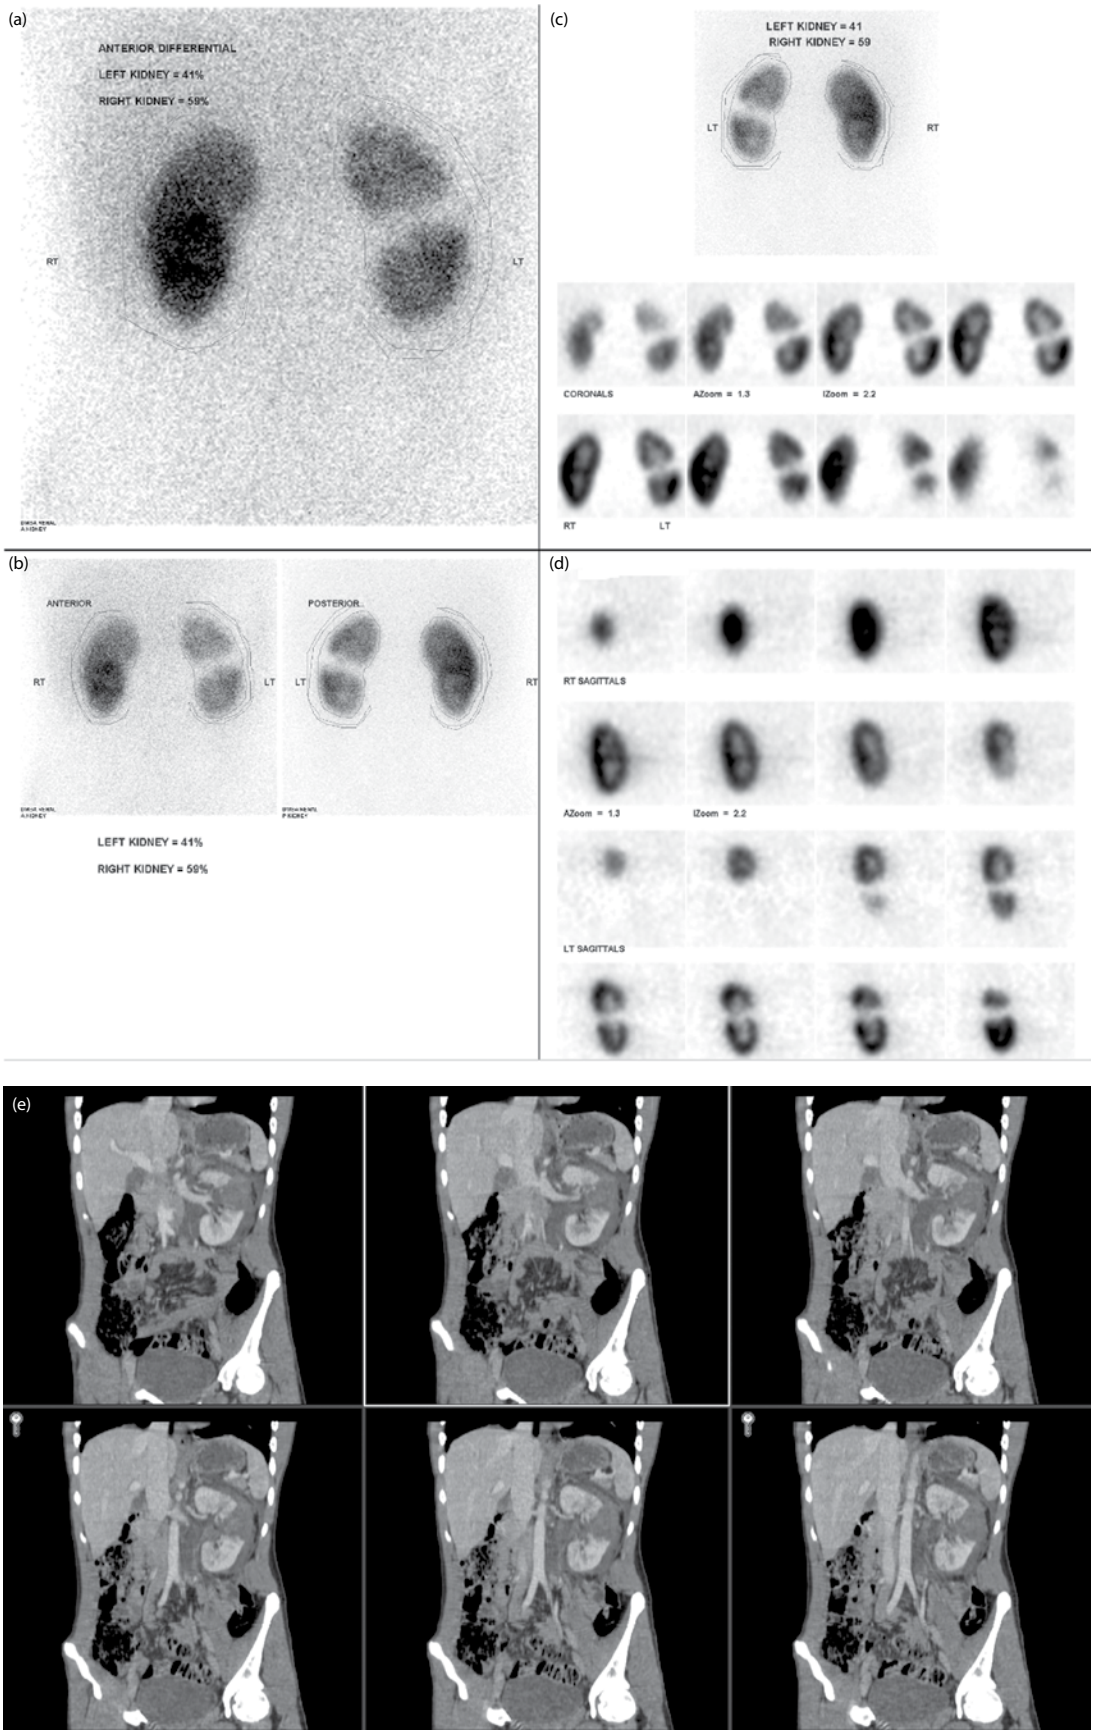

FIGURE 5.12 DMSA renal scan in a patient after a blunt trauma. Planar (a) and SPECT (c and d) views show a band-shaped cortical defect in the left kidney. (b) The differential function is decreased in the left kidney. (e) CT scan coronal views in the same patient.

The pre-ACEI scan is similar to a standard renography. For the post-ACEI study, the same radiotracer is injected either 1 hour after oral ingestion of captopril or 15 minutes after intravenous injection of enalaprilat. It is essential to monitor the blood pressure before the study both for patient safety and to avoid ACEI-induced hypotension that could be a source of a false-positive result. Compared with the pre-ACEI scan, decreased cortical uptake (or decreased GFR) on post-ACEI study with ^{99m}Tc-DTPA is suggestive of hemodynamically significant renal artery stenosis. When using ^{99m}Tc-MAG3, increased parenchymal retention (including increase in the transit time and increase in the ratio of the peak to 20 minutes' activity) and sometimes decreased cortical uptake and delay in the excretion of the radiotracer into the calyceal system, in comparison with the pre-ACEI study, are suggestive of hemodynamically significant renal artery stenosis. In the case of bilateral changes after ACEI, other possibilities, such as ACEI-induced hypotension, and dehydration, should also be considered.

Instances of subsegmental or segmental renal artery stenosis may be difficult to detect by ACE inhibition renography. In these instances, a subsegmental or segmental reduction may be seen on a ^{99m}Tc-DMSA cortical renal scan.

ACUTE KIDNEY LESIONS

Acute kidney lesions are usually related to intravascular hypovolemia with reduced renal perfusion. The extent of the renal damage depends on the severity of the underlying clinical problem. The renal scan (including angiogram phase) is useful in various pathologic states, such as tubular necrosis, cortical necrosis, and renal vein thrombosis. The interpretation of the scan, however, must be made in light of the clinical circumstances, since other entities, such as acute glomerulonephritis, can look somewhat similar.

Children with *acute tubular necrosis* generally show good perfusion to the involved kidney. However, there is delayed excretion because radioactivity is retained within the renal parenchyma, and often no activity is seen in the bladder by 30 minutes. There is no dilatation of the collecting systems to suggest hydronephrosis. In neonates, asphyxiated bladder syndrome may coexist and consists of gross bladder distension with urinary retention. Urate nephropathy of the newborn will look similar because it also causes intratubular obstruction. However, an episode of circulatory compromise is usually present to distinguish acute tubular necrosis.

In *renal vein thrombosis*, depending on the severity and stage of resolution, variable appearance may be seen. Usually, there is a poor perfusion to an enlarged kidney with poor excretion (increased cortical retention). In pediatrics, renal vein thrombosis may be seen as a complication of nephritic syndrome. It is often difficult to distinguish renal vein thrombosis from an arterial problem or intrarenal vascular problem, and this diagnosis should usually be confirmed by contrast angiography or Doppler ultrasound.

MEASUREMENT OF GFR

Measurement of serum Cr or blood urea nitrogen (BUN) is a simple method for the evaluation of renal function. However, renal function has to be reduced significantly before any changes in BUN or Cr are detected. Serum Cr and BUN determination are not so accurate in acute changes of renal function, in different metabolic states, when there are differences in muscle mass, and after some medications. Cystatin C seems to have advantages over serum Cr measurement in pediatric populations. However, it may be influenced by other factors, including weight, height, and serum C-reactive protein.[36]

GFR is the most useful quantitative index of renal function and is used clinically as the gold standard of renal function. GFR can be calculated based on serum Cr level or other serum markers. Different formulas for the calculation of GFR, including Schwartz or Counahan–Barratt, have at least 10%–20% error.[36] Follow-up of patients with impaired renal function requires reliable measurements of GFR. Inuline clearance is the gold standard for the GFR measurement, but it is not practical clinically.

Evaluation of GFR with the nuclear medicine method is accurate and precise. The results are reproducible, so the patients can be followed by this method. Many radiotracers have been used for the evaluation of GFR in nuclear medicine, including ^{125}I-iothalamate, ^{51}Cr-EDTA, and ^{99m}Tc-DTPA. DTPA is the most widely used radiotracer for GFR measurement in North America. In Europe, EDTA is the most commonly used agent. When ^{99m}Tc-DTPA is used, it is possible to do GFR measurement and DTPA renogram study, concomitantly.

There are numerous methods for evaluation of GFR after injection of Tc-DTPA, which are usually categorized into camera-based methods and blood sampling methods. In camera methods, there is no need to do blood sampling and the time of study is shorter; however, it is not as accurate as sampling methods. Radionuclide GFR measurement with blood sampling is used frequently for accurate dose adjustment of chemotherapy (Figure 5.13), for monitoring of drugs that might cause nephrotoxicity, in transplanted kidney for evaluation of rejection, and in assessment of potential live donors for transplantation.[37]

SCROTAL IMAGING

Ultrasound is the method of choice for the evaluation of a painless or chronic scrotal mass. However, in acute scrotal pain, scrotal scintigraphy could be useful to differentiate the underlying pathologies, especially if the result of ultrasound is equivocal. In scrotal scintigraphy after injection of Tc-pertechnetate, sequential anterior static views are obtained for 15–20 minutes after 1-minute dynamic flow images. In *acute torsion*, the early perfusion to the affected testis may be normal, although a small hyperactive focus, a nubbin sign, may be seen proximal to the obstructed vessels. However, on delayed static images, the activity in the affected testis is usually decreased. In a *missed torsion* (delayed torsion), the activity in the affected testis is decreased (infarcted photopenic testis) with a rim of radiotracer accumulation

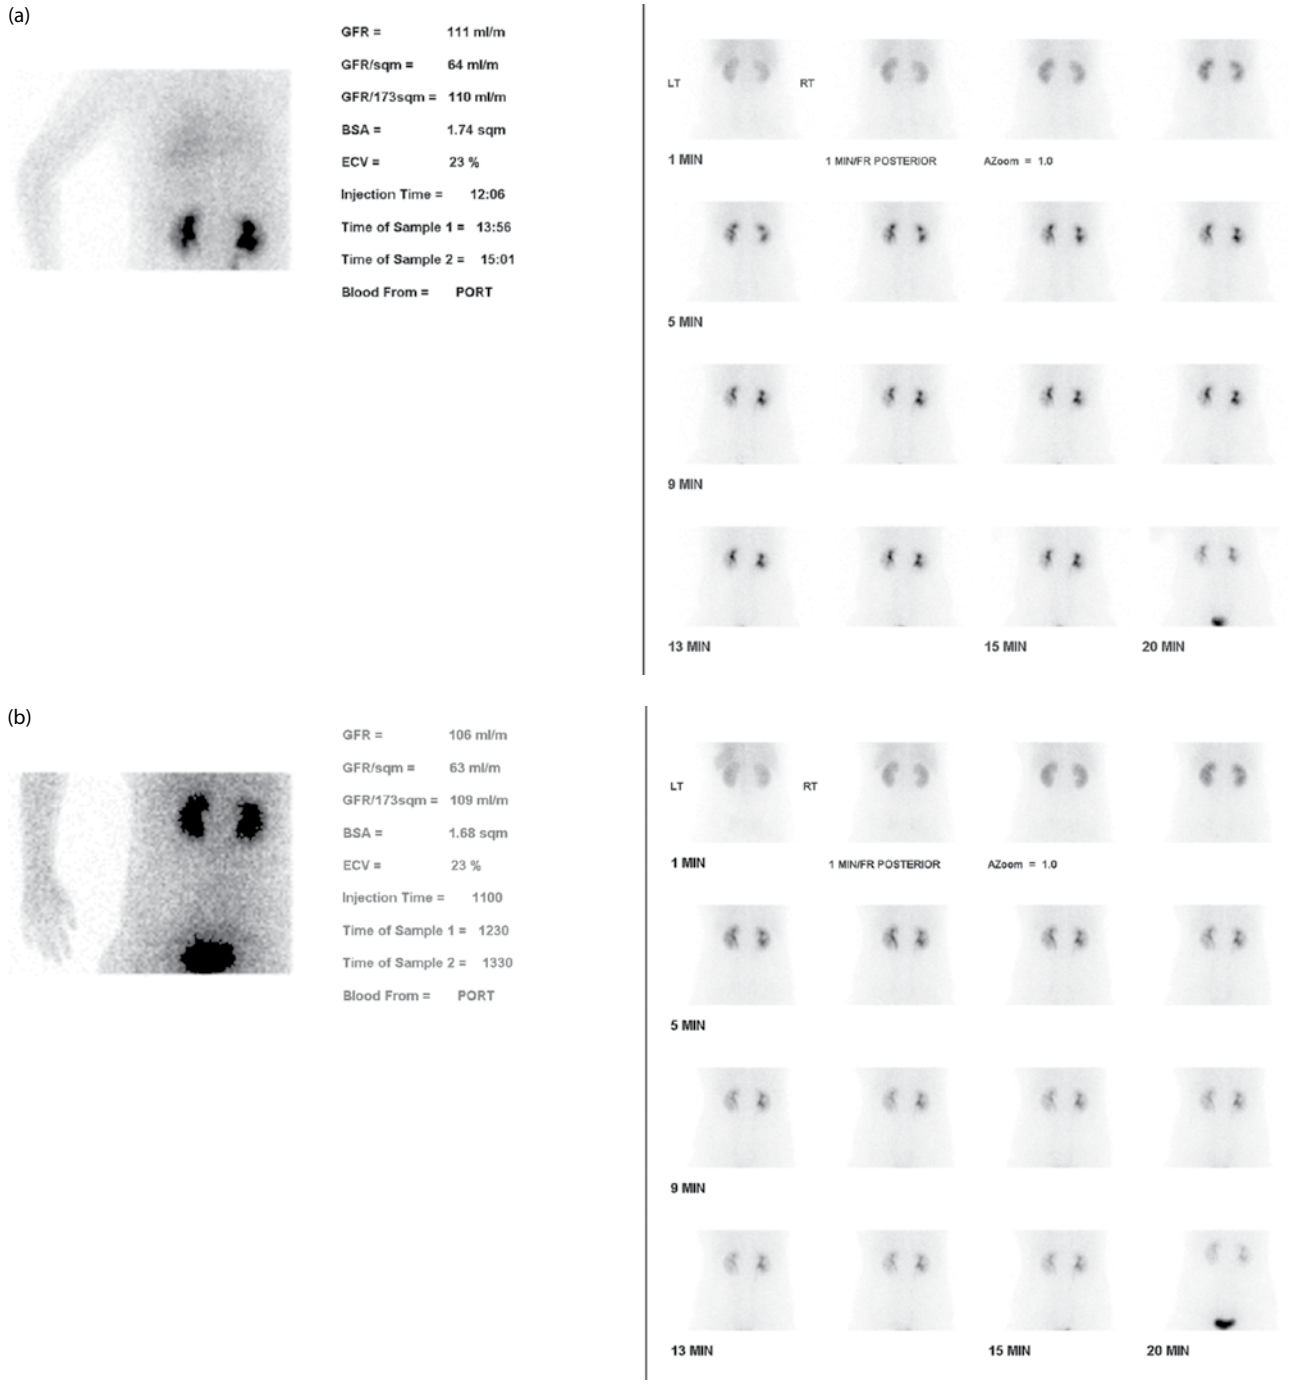

FIGURE 5.13 (a) GFR study in a 14-year-old girl with osteosarcoma of the right leg. (b) Three months after chemotherapy and a high dose of methotrexate, the GFR study was repeated to monitor the kidney function. The GFR values remained unchanged.

due to increased perfusion to the hemiscrotum (a donut pattern). In *epididymo-orchitis*, both perfusion and delayed images show increased activity on the affected side.

NUCLEAR MEDICINE IN GENITOURINARY TUMORS

Advances in molecular oncology, diagnostic imaging, surgical approaches, and stem cell transplantation have improved the survival rate of pediatric genitourinary tumors.[38] Conventional nuclear medicine procedures have an important role in the management of pediatric uro-oncology. The ^{123}I- or ^{131}I-metaiodobenzylguanidine (MIBG) scan has been used for a long time with a high sensitivity and specificity for the detection, staging, and follow-up of neuroblastoma (Figure 5.14). A bone scan is useful when bone metastasis is suspected. It has a complementary role to the MIBG scan in neuroblastoma. When differentiation of a renal tumor versus hypertrophic Bertin columns is of interest, cortical imaging with DMSA is

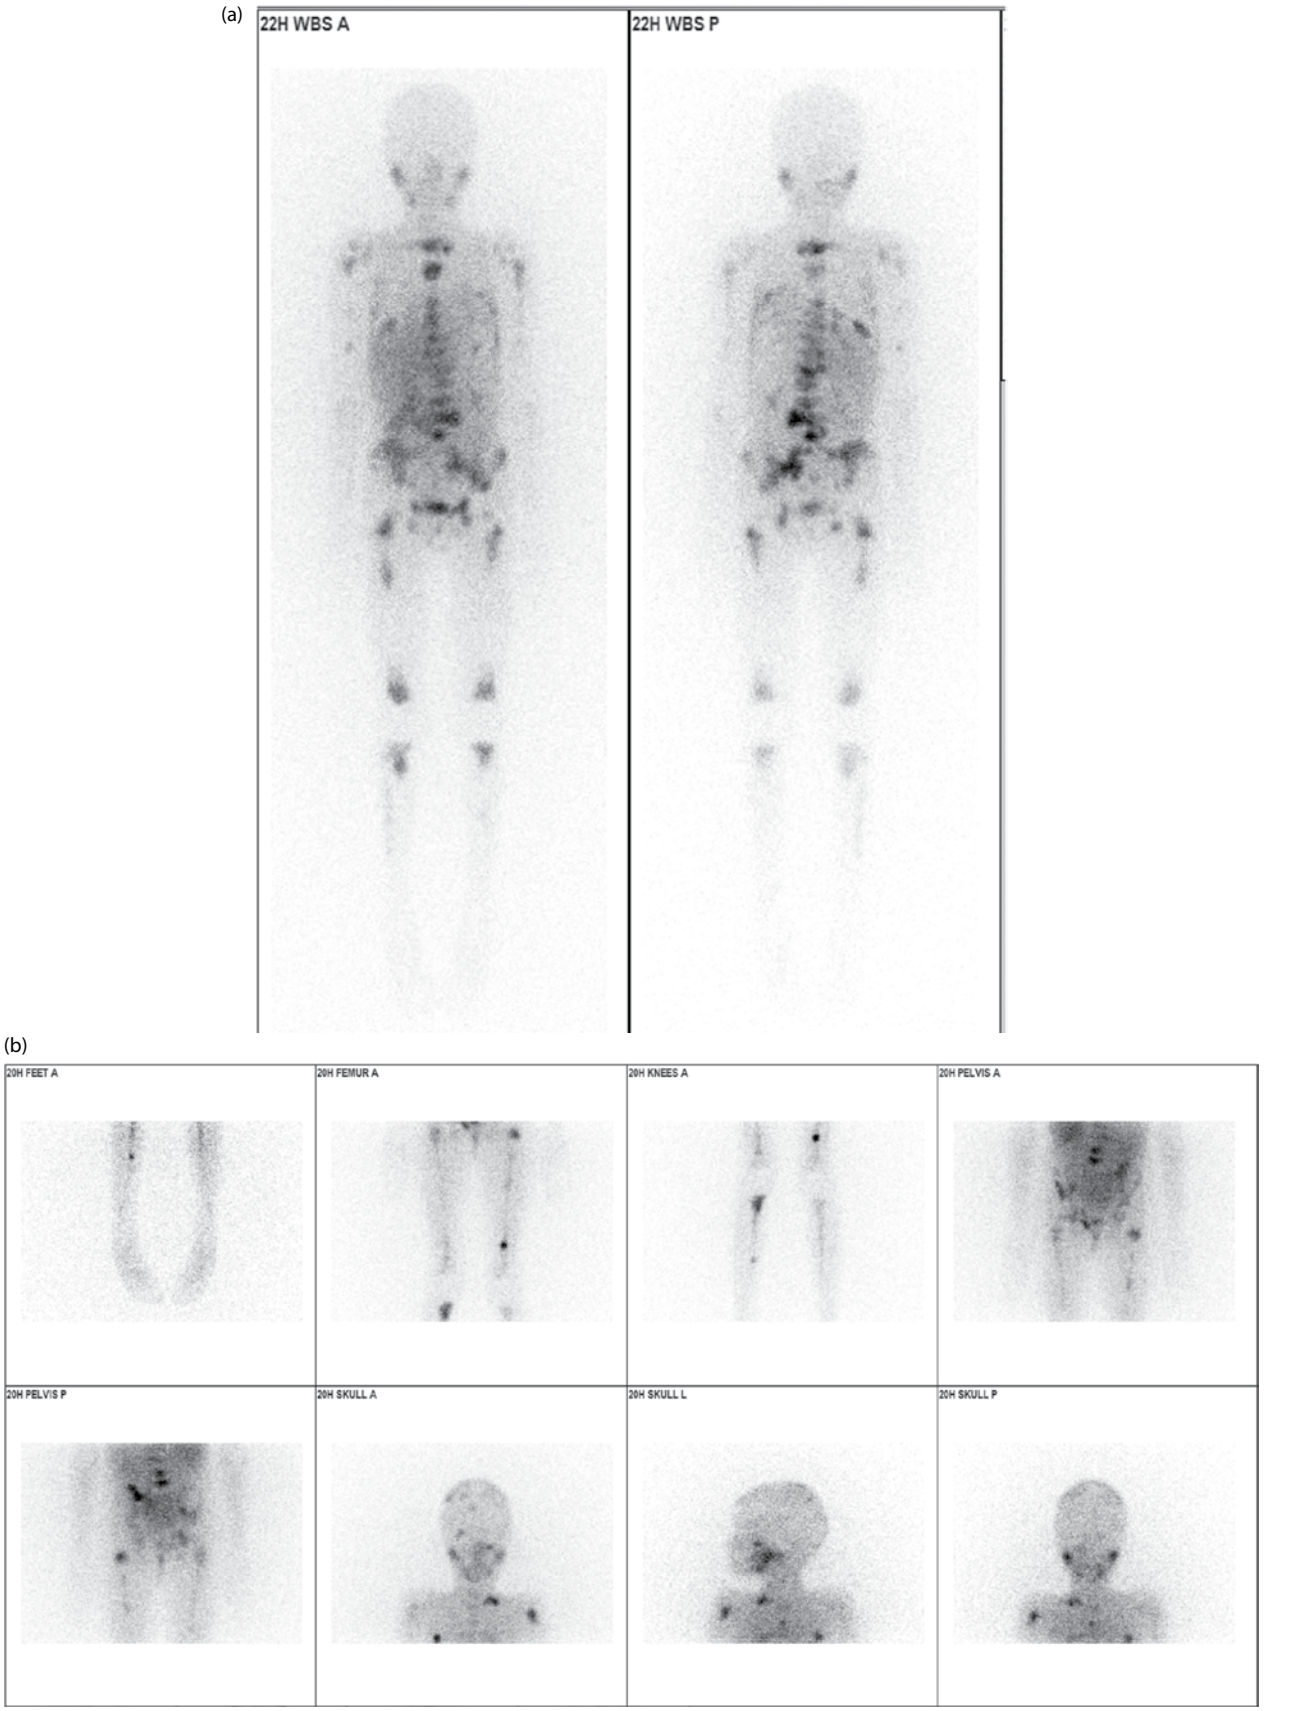

FIGURE 5.14 MIBG scan in a 9-year-old patient. Whole-body anterior and posterior images (a) and spot views (b) show multiple foci of MIBG-avid lesions in the skull, sternum, humeri, ribs, vertebrae, pelvis, femurs, tibias, left supraclavicular lymph nodes, and abdominal and pelvic paravertebral lesions.

helpful. The decision of whether to do a nephrectomy or a reconstructive procedure may be a difficult one, especially in the child whose contralateral kidney is already jeopardized. One of the factors influencing this decision is the degree of function of the affected kidney. A MAG3 renal scan or DMSA cortical scintigraphy can be helpful in this scenario.

The application of ^{18}F-fluorodeoxyglucose (^{18}F-FDG) PET in pediatric genitourinary cancer is limited. It does not appear to be useful in the initial diagnosis of primary bladder and kidney tumors. However, if the diagnosis of renal cell carcinoma, it is useful to detect the metastasis at the initial diagnosis, staging and restaging, diagnosis of residual renal fossa masses following nephrectomy, and assessment of response to therapy.[39] In testicular germ cell tumors, FDG PET is a very useful method for pretreatment staging and to evaluate posttreatment residual masses. It has a higher diagnostic accuracy than CT for both staging and restaging and should be the test of choice for the assessment of a CT-visualized residual mass following chemotherapy.[39] FDG PET/CT is a valuable tool for initial staging of pediatric rhabdomyosarcoma patients, and seems to be an additional predictor of outcome.[40] New somatostatin receptor PET tracers, such as ^{68}Ga-DOTA-TOC, have very high sensitivity for detection of the neuroendocrine tumors, including neuroblastoma.[41,42] In all kind of tumors, ^{18}F-FDG is valuable to differentiate fibrosis from recurrent disease in the treatment bed, an area of difficulty for CT/MRI.

Neuroblastoma

Neuroblastoma is the most common extracranial solid tumor in infants and children, accounting for 7.6% of all childhood cancers. Approximately half of newly diagnosed neuroblastomas are encountered between ages 1 and 4 years. Despite extensive ongoing clinical and basic science research, neuroblastoma remains an unknown tumor with unpredictable clinical behavior. ^{131}I- or ^{123}I-MIBG is the conventional agent for detection of neuroblastoma with a high sensitivity and specificity. MIBG binds mostly to the presynaptic sympathetic receptors and is actively transported to the intracellular structures predominantly by a type I amine uptake mechanism. As a result, a wide range of over-the-counter and prescribed medications may interfere with the MIBG uptake and should be discontinued before MIBG diagnostic imaging or therapy.[43,44] Whole-body images are obtained 24 and 48 hours after administration of MIBG. SPECT images are also acquired after administration of ^{123}I-MIBG and may help to detect the lesions behind the heart and the liver and better localize the tumor (Figure 5.15). MIBG is positive not only in primary tumor but also in metastatic lesions, including bone

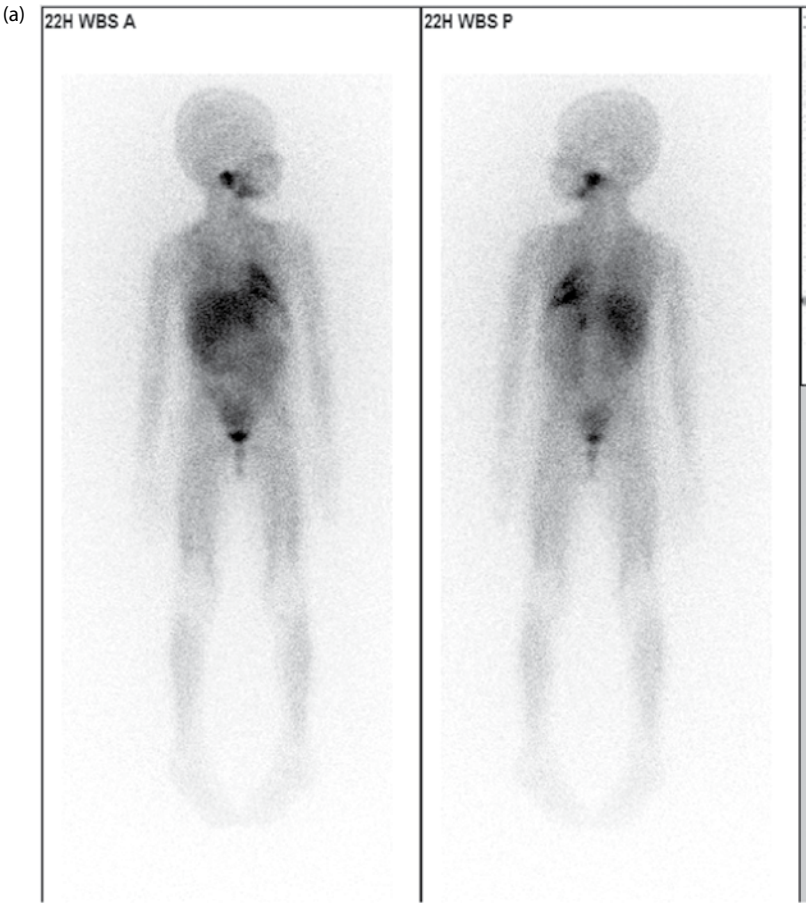

FIGURE 5.15 MIBG scan in a patient with a thoracic neuroblastoma located behind the heart. (a) Whole-body images did not show any abnormality. (*Continued*)

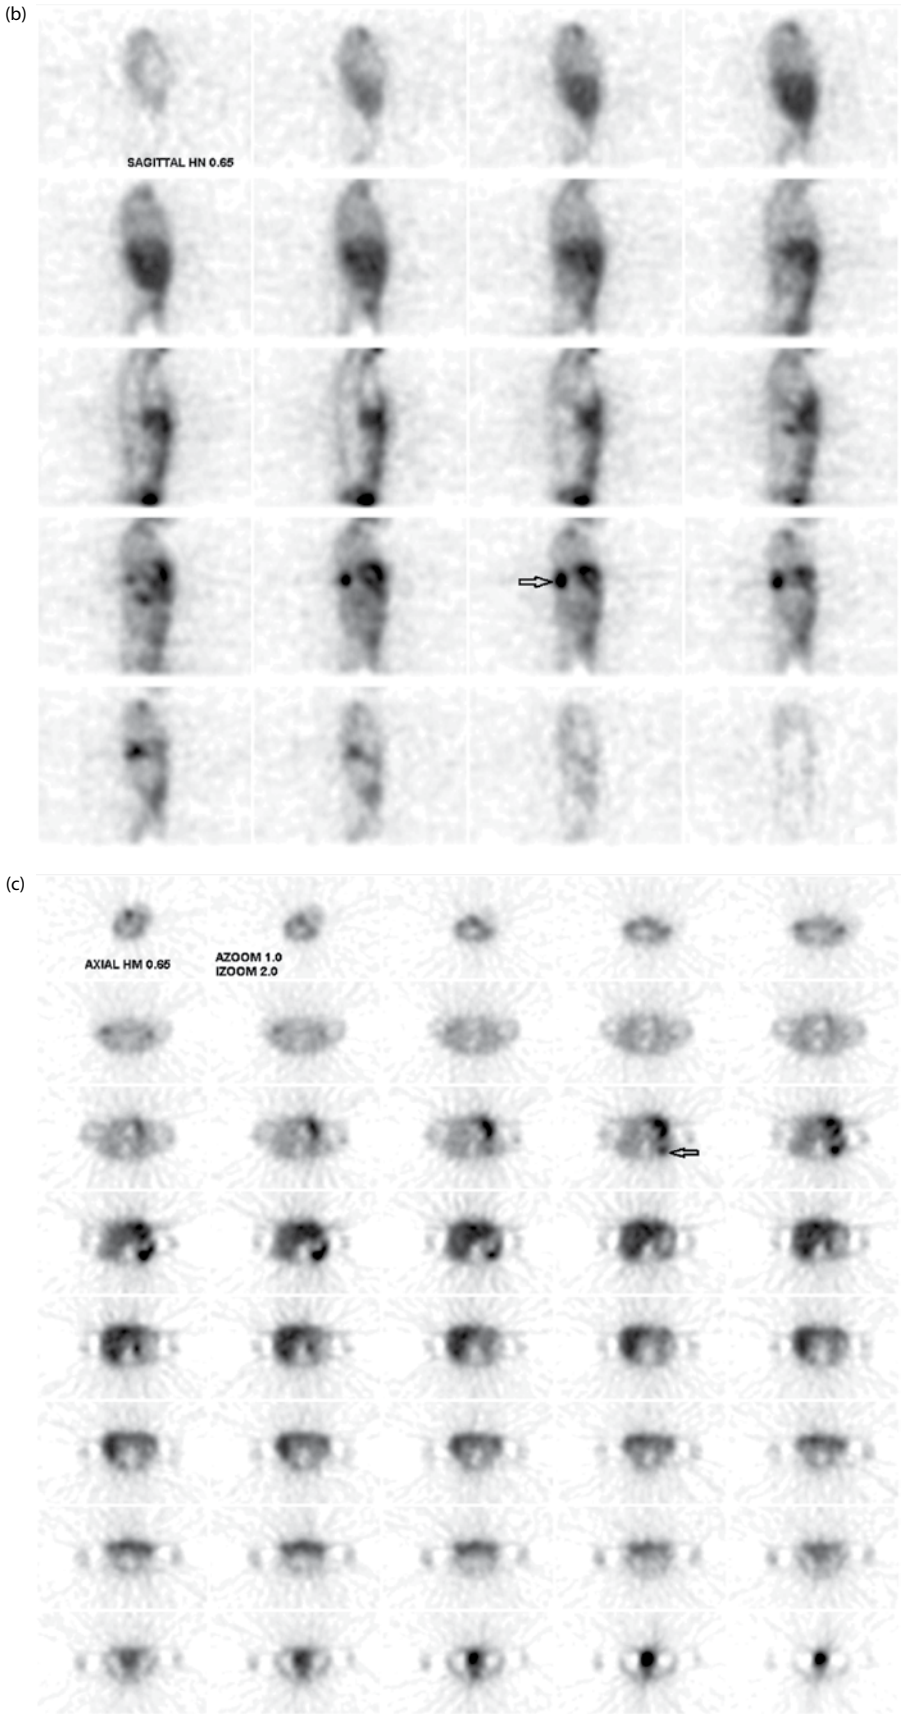

FIGURE 5.15 (Continued) (b and c) On SPECT study, there was a large focus on MIBG activity corresponding to a thoracic mass behind the heart. SPECT study is especially useful in the chest and abdomen to detect the lesions behind or around the organs with physiologic uptake or excretion of the radiotracer.

and bone marrow involvement. The sensitivity of MIBG is higher than that of a bone scan to detect bone metastases. However, in some cases a bone scan may reveal bone metastases that fail to show MIBG uptake. Currently, the MIBG study is indicated for the evaluation of neuroblastoma at presentation, for restaging after treatment, to detect postsurgical residual tumors, for monitoring the effect of treatment, and for early diagnosis of recurrence at follow-up.[45]

Somatostatin receptor scintigraphy (SRS) and ^{18}F-FDG PET are also used for evaluation of neuroblastoma. The sensitivity of SRS (e.g., ^{111}In-octreotide) is higher than that of ^{123}I-MIBG and ^{18}F-FDG in other neuroendocrine tumors. However, MIBG is more sensitive for neuroblastoma. ^{18}F-FDG PET is probably more sensitive when the tumor cells have a high proliferation index (Figure 5.16).[46] Nuclear medicine techniques, including ^{123}I or ^{131}I-MIBG, ^{111}In-DTPA octreotide, somatostatin receptor imaging (^{68}Ga-DOTA-TOC or ^{68}Ga-DOTA-TATE) PET/CT, ^{18}F-FDG PET/CT, and radionuclide therapy with ^{131}I-MIBG, ^{177}Lu-DOTA-TATE, and ^{90}Y-DOTA-TATE, play a major role in the management of neuroblastoma and neuroendocrine tumors.[47]

Wilms' Tumor

Wilms' tumor is the most common childhood renal tumor, accounting for approximately 6% of all pediatric malignancies. The peak age in pediatrics is between ages 1 and 3 years, with 90% of new cases diagnosed before age 7 years. A CT scan of the abdomen has been the standard diagnostic modality. Due to the urinary excretion of FDG, ^{18}F-FDG PET has a limited role in the detection of the Wilms' tumor or differentiation of the tumor from an infectious process. However, it is useful in the restaging of the patients and/or detection of distant metastasis.[39]

FUTURE INVESTIGATIONS

Future directions of renal PET imaging will be the quantitative assessment of renal blood flow with ^{15}O-labeled water, ^{13}N-labeled ammonia, and ^{82}Rb in renovascular hypertension, transplanted kidneys, and drug-induced nephropathy, and the assessment of response to revascularization. The roles of molecular imaging, receptors and oncoproteins, apoptosis, and stem cell kinetics are under investigation.[1,47]

CHAPTER

6

Prenatal and Postnatal Urologic Emergencies

Fernando Ferrer and Patrick H. McKenna

INTRODUCTION

The widespread availability of accurate imaging and genetic screening, and the active participation of pediatric urologists in a multidisciplinary approach to urologic problems have resulted in their detection during fetal development. Consequently, there are few true urologic emergencies since foresight offers the opportunity for counseling parents and planning treatment. As technology and genetic understanding continue to advance, the frequency with which diseases are identified in the prenatal period will continue to increase. These advances have and will continue to present difficult ethical and societal issues to the pediatric urologist, when the abnormalities discovered prenatally are severe enough to warrant consideration of prenatal intervention, possibly even termination of pregnancy. In this chapter, an overview of a variety of urological conditions presenting prenatally and during the first year of life only is offered. An emphasis is placed on information particularly useful to guide the consultative process. We begin by focusing on conditions that might be managed prenatally, and conclude with those for which management must be delayed—or are not recognized—until after birth.

DETECTION OF UROLOGICAL ABNORMALITIES

Routine prenatal ultrasound screening occurs in an obstetrical office using standard two-dimensional (2-D) ultrasound. Inexpensive, readily available, and of high-quality, routine 2-D sonography detects a congenital anomaly in 1%–2% of pregnancies, with up to 20% of these involving urologic conditions.[1–4]

Increasing dilation of the renal pelvis correlates with a greater likelihood of obstruction,[5,6] and in utero progression of mild hydronephrosis is rare, usually less than 15%.[7] Lack of dynamic change in anteroposterior renal pelvis measurement with a change from prone to supine position may also support the diagnosis of significant obstruction.[8] Additionally, increased echogenicity of the renal cortex and decreased amniotic fluid volume have been correlated to impaired postnatal renal function.[9] Findings suggestive of specific diagnoses are provided in Table 6.1. Accurate sonographic imaging may require infusion of fluid into the amniotic space if severe oligohydramnios exists.

However, newer imaging technologies, such as three-dimensional (3-D) ultrasound and fetal magnetic resonance imaging (MRI), are increasingly used to provide greater detail of anomalies identified by 2-D ultrasound.[10] Fetal MRI has expanded its indications and availability but is still expensive and highly specialized compared with ultrasonography. MRI can provide additional anatomic detail that may facilitate prediction of future renal function,[11] especially when oligohydramnios impairs ultrasound quality.[12–16] When anatomy is complex or standard sonography is inconclusive, MRI has been found to change management in up to 33% of cases.[17,18]

Ultrasound still has limitations,[19] and fetal MRI is an emerging modality for evaluating prenatal urologic conditions and associated anomalies.[17,20] Fetal MRI may be particularly helpful when amniotic fluid levels are low or to provide additional prognostic information on renal function.[12–16] Any imaging must be considered in light of other factors.

When the urological condition has been identified only after birth, physicians need to consider the unique aspects of bonding between the infant and the parents.[21–23] Bonding can be negatively impacted by the abnormality itself and by any undue separation of the infant from the parents.[24–26] Prenatal counseling may aid in bonding.[23] These considerations should impact the treatment of infants with and without obvious congenital abnormalities. The support should extend beyond helping the family understand the anomaly, and should include managing parental fears concerning job loss, financial difficulties, and effects on other family members.[24] Early discharge of infants who can be adequately managed as outpatients is

TABLE 6.1 Prenatal ultrasound findings suggestive of specific diagnoses

Round symmetrically thick-walled bladder	Complete urethral obstruction (atresia or PUV)
Elongated/tubular bladder, symmetrically thick wall	Partial urethral obstruction (stricture or PUV)
Elongated/segmented or “snowman” bladder	Urethral hypoplasia (i.e., prune belly syndrome)
Dilated proximal urethra or keyhole sign	PUV, or possibly more distal lesion

encouraged. When prolonged hospitalization is required, parental rooming in with the infant is encouraged. A psychiatrist and staff educated on bonding issues should be actively involved in patient and parental management.[27–30]

PRENATAL INTERVENTION

Although still rare, the incidence of prenatal surgical intervention, including medical treatment, termination of pregnancy, early induction of delivery, and surgical intervention, is increasing. There are complex ethical, technical, and medical issues surrounding all forms of prenatal intervention.[31–33] These issues are especially important in countries such as the United States, where there is a time limit on the gestational age when elective termination can be performed. However, even in countries with few legal restrictions on termination throughout pregnancy, accuracy of the prenatal diagnosis and a correct explanation of the long-term outcomes are foundational to informed decision making.[34] The difficult task is providing an accurate assessment of the quality of life for patients with severe congenital abnormalities so that parents can make an educated decision about intervention or pregnancy termination. Many centers have established multidisciplinary teams comprised of dedicated providers representing maternal–fetal medicine, pediatric anesthesia, pediatric surgery, pediatric radiology, pediatric urology, and pediatric nursing to adequately address the full scope of care for the mother and child.[35]

The conditions pertinent to a pediatric urologist most likely to be considered for prenatal intervention include lower urinary tract obstruction (LUTO), congenital adrenal hyperplasia (CAH), and open neural tube defects. The flow diagram in Figure 6.1 is designed to focus on the importance of oligohydramnios when considering intervention. If the flow diagram is followed, few patients will be considered for prenatal intervention. The remaining conditions, while increasingly diagnosed prenatally, are treated after birth.

COMPLICATIONS OF PRENATAL INTERVENTION

Intervention in the prenatal period can take various forms, from medical treatment to surgical intervention. The consequences of prenatal medical treatment for CAH exemplify some of the ethical and practical problems with prenatal

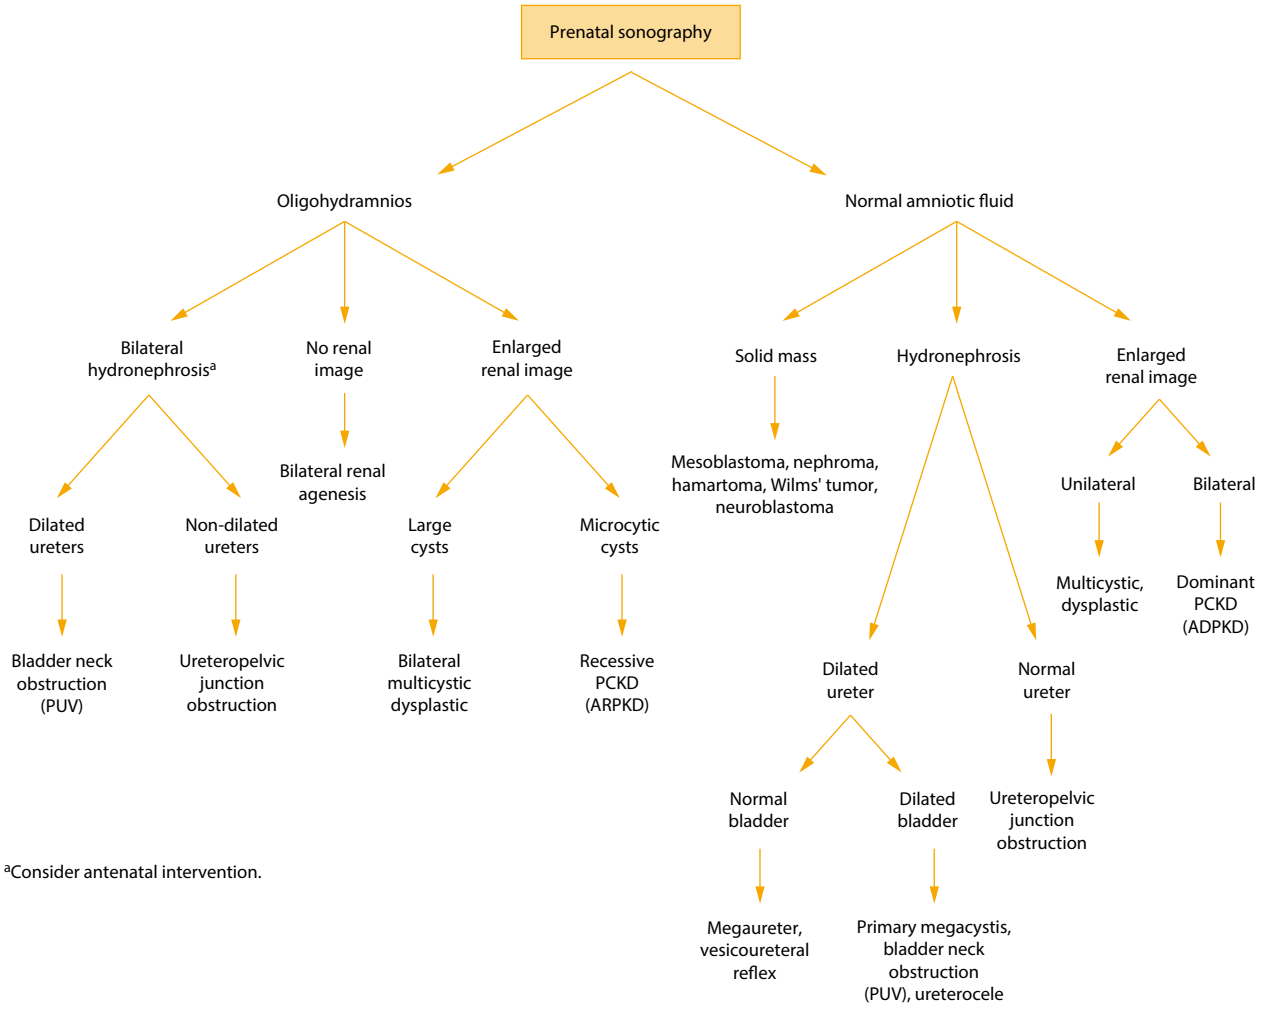

FIGURE 6.1 Prenatal flow diagram. PCKD, polycystic kidney disease.

treatment of the fetus with medication and are discussed in that section of this chapter. The risks to the fetus escalate the more invasive the form of prenatal intervention.

Minimally invasive procedures, such as amniocentesis, are often needed to establish a diagnosis and may need to be repeated during pregnancy. Amniocentesis during the second trimester has become almost a routine procedure. When it is done with ultrasound guidance, there is a 1% incidence of spontaneous abortion.[36–38] Fetal hemorrhage, cord laceration, direct fetal injury, uterine injury, chorioamnionitis, amniotic fluid leak, and talipes equinovarus (club foot) have been reported after amniocentesis. But, when amniocentesis is performed using specific guidelines by experienced teams, these risks are minimized.[39–41]

Chorionic villus sampling (CVS) historically had a fetal loss rate of approximately 3.5% and infection rates of 0.25%–0.5%, although a recent review shows rates similar to those for amniocentesis.[36,42,43] Very early CVS, around 7 weeks' gestational age, carries an increased risk of fetal limb reduction defects of 1%,[44,45] but by 10 weeks, the rates equal those of the general population.[43,46] Recent data suggest that CVS may be safer than early amniocentesis,[47] and current consensus supports CVS as the preferred option prior to 13 weeks.[48,49] In recent years, screening protocols combining maternal age, fetal ultrasound, and serum markers, such as β-human chorionic gonadotropin (β-hCG) and plasma protein A, have led to a reduction in the use of invasive testing.[50] This trend will likely continue as more accurate noninvasive testing is developed.

More invasive intervention, including percutaneous procedures and open surgery, are associated with more significant problems. The main urological abnormalities currently considered for intervention include fetal urinary tract obstruction and myelomeningocele repair.[51,52] Even the most invasive procedures have minimal maternal risks or effect on future maternal fertility.[53] Common complications of prenatal urologic intervention by hysterotomy or percutaneous access include uterine contractions with premature delivery, chorioamnionitis, fetal or maternal injury, and fetal loss, in addition to any procedure-specific risks, such as shunt migration.[54–56] The increased use of percutaneous laparoscopic surgery with or without robotic assistance may decrease the problems of uncontrolled uterine contractions. However, laparoscopy carries the risk of percutaneous access wounds, including injury to other fetal organs and to the abdominal wall.[57–66]

Development of better tocolytic agents and other methods to prevent uterine contraction is crucial to successful prenatal surgery. New research into changes on the cellular level after fetal intervention may help guide therapy to prevent complications.[67] Once intervention is anticipated, the pediatric team, including the maternal–fetal obstetrician, pediatric urologist, and neonatologist, should be available because complications such as uncontrolled uterine contraction or serious fetal injury may require immediate delivery, infant resuscitation, or surgical intervention.[68]

TERMINATION OF PREGNANCY

The increased detection of fetal anomalies has led to increased rates of termination of pregnancy for fetal anomalies (TOPFA).[69] A broad spectrum of prenatally diagnosed conditions may lead to a decision to terminate the pregnancy, including severe genetic defects; universally fatal conditions, such as anencephaly or isolated structural (i.e., cardiac) or mental (i.e., Down's syndrome) conditions; or conditions with late-term morbidity, such as Huntington's disease, while urological conditions are rarely among reasons for TOPFA. When encountered, prenatal counseling for severe urological conditions must also consider the long-term quality of life issues against the ethical, psychosocial, and medical risks for TOPFA.

Rates of TOPFA increase according to the severity of the condition.[70,71] There are significant differences in rates of TOPFA, particularly late-term TOPFA (occurring after 22–24 weeks' gestational age) between countries, as well as regional differences within countries.[69,72] France has the highest rate of late-term TOPFA at 2.65 per 1000 live births, which is likely influenced by the accessibility of prenatal screening and greater legal acceptance of late TOPFA compared with other countries.[72] Religious and socioeconomic factors also have a significant impact on patient and provider views regarding TOPFA.[70,73]

The ethical and moral issues surrounding TOPFA are complex, and many are unique, as prenatal medicine is the only field in which termination is presented as a treatment option.[74] Nearly one-third of prenatally detected abnormalities may not be detected until near or after the gestational age limit for legal abortions of 22–24 weeks.[75] This leaves parents little time when faced with this difficult decision. The legal framework surrounding TOPFA late in pregnancy varies greatly by country, but there is a general trend toward increased legalization.[76] Many of the current laws and professional guidelines were set before current diagnostic techniques, and a significant number of laypersons and medical practitioners feel that they are inadequate today.[77–80]

Termination of a pregnancy carries great potential for psychological and emotional stress for the parents and medical staff involved. Postpartum depression can occur in up to one-third of patients, three times the expected rate after an uncomplicated birth, and are higher in younger women.[81] Many women feel inadequately prepared regarding the various choices they would have to make and the potential difficulties that may be encountered during the process.[82] Physicians themselves report that they often do not address difficult issues, such as the possibility of feticide or that the fetus may survive the procedure.[34] Fetal survival of the termination procedure can be a particularly distressing scenario, and medical personnel need to be prepared for this possibility if feticide is not carried out prior to delivery late in pregnancy. The spectrum of responses to a live-born fetus following a termination procedure ranges from full neonatal intensive care (NICU) unit resuscitation efforts to euthanization.[34] Protocols for feticide, typically by intracardiac injection of potassium chloride, have been proposed by individuals and professional organizations for any planned TOPFA after 22 weeks' gestational age to avoid the possibility of a live birth.[79]

Improved early detection and increased access to screening may decrease the rates of late TOPFA, but the moral debate will likely continue. Medical advances in fetal imaging and improved premature infant survival

have blurred the line between fetus and newborn. This phenomenon has simultaneously "fetalized" newborns, on the one hand, and personalized fetuses, on the other, and has been used as justification for both the euthanization of newborns, if they are not that different from fetuses, and increased restrictions on pregnancy terminations.[83] The gravity and complexity of these issues must be appreciated by the urologist whenever conducting prenatal counseling in which the termination of a pregnancy may be an option.

OBSTRUCTIVE UROPATHY WITH OLIGOHYDRAMNIOS

According to the Society for Fetal Urology consensus statement from 2010, prenatal hydronephrosis may be detected in up to 5% of pregnancies.[84] However, most cases are mild with a low incidence of true urologic pathology, and only 1 in 30,000 pregnancies is estimated to be a potential candidate for prenatal intervention because of an obstructive lesion.[5,68,85–88] Urethral atresia is the most common cause of early severe hydroureteronephrosis. Posterior urethral valves (PUVs) (Figure 6.2) may present either early or late in the pregnancy with varying degrees of renal injury. A ureterocele obstructing the bladder neck due to a ball valve mechanism is another rare form of bladder neck obstruction more common in females.[89] Obstruction from any of these lesions causing oligohydramnios remains rare, and pediatric urologists continue to have a role in preventing unnecessary prenatal intervention.

The negative impact of early severe obstruction on lung development has been well documented.[90–94] After early animal studies showed promise for prenatal intervention to improve the deleterious effects of LUTO on renal and pulmonary development,[90,95,96] numerous trials of vesicoamniotic shunts (VASs) (Figure 6.3) on human fetuses have been performed since the early 1980s.[56] Unfortunately, outcomes after intervention in humans have been more mixed.

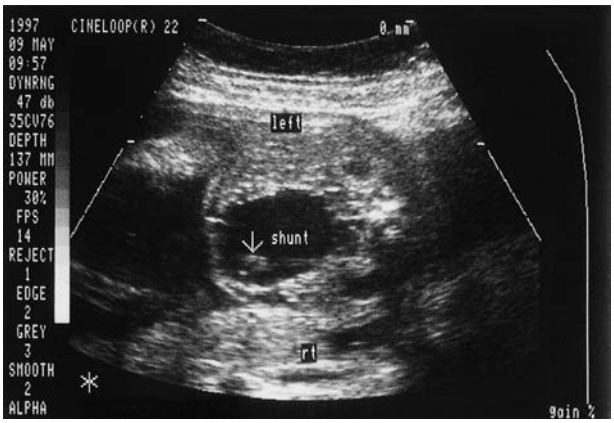

FIGURE 6.3 Antenatally detected PUVs with percutaneously placed VAS.

Limited data from early studies of prenatal intervention for human fetal uropathies supported the efficacy of intervention,[88,97–102] but data were limited in size and quality. Published reports concerning the results of intervention are mostly retrospective in nature without long-term follow-up.[56,103] In addition, the natural history of these lesions differs in the timing of presentation and their severity, even during the prenatal period, making case comparisons difficult.[56,104]

The largest systematic review to date on outcomes after prenatal intervention for LUTO showed improved perinatal survival with intervention (odds ratio [OR] 3.82%, 95% confidence interval [CI] 2.14–6.82), with the largest effect seen in the group with the poorest pretreatment prognosis. Only those with the best pretreatment prognosis appear to show improved survival with normal renal function, but this was not statistically significant (OR 2.98%, 95% CI 0.45–19.62). When all prognostic groups were included, there was actually a trend favoring no treatment, again not statistically significant (OR 0.67%, 95% CI 0.22–2.00).[56] Simple diversion does not

appear to be adequate to completely prevent or reverse the effects of LUTO.

VAS also carries a significant rate of complications, such as shunt migration (34%), preterm premature rupture of membranes, chorioamnionitis, and fetal death.[56] Fetal cystoscopy with valve ablation has been performed since the mid-1990s in an attempt to establish more natural bladder cycling, provide a more accurate diagnosis, and avoid complications, such as shunt migration. To date, no significant benefit has been shown over VAS, but numbers are small and no randomized controlled trials have been performed.[65]

Selection criteria to consider that will maximize the potential benefit to treatment generally include (1) karyotype excluding chromosomal abnormalities and demonstrating male sex; (2) exclusion of other significant structural abnormalities that may negatively impact prognosis; (3) oligohydramnios or anhydramnios; (4) singleton pregnancy; (5) sonographic evidence of obstruction, such as bilateral hydronephrosis, megacystis, or renal changes; and (6) evidence of recoverable renal function.[105] Female fetuses are typically excluded because obstruction usually accompanies more complicated developmental abnormalities and intervention has not been shown to improve outcomes in those cases. Serial sampling of fetal urine by repeat vesicocentesis should be used to assess renal function, but carries the obvious risks to the fetus and mother (see section on Complications of Prenatal Intervention). Various predictors of renal function are presented in Table 6.2. Sodium and calcium appear to be the most accurate at predicting poor renal function,[106] but precision is still lacking. Fetuses with the best prognosis have the strongest indications for intervention.

Fetuses otherwise meeting inclusion criteria, but with borderline urine analyte levels, may benefit from intervention that may reduce the risk of fatal pulmonary hypoplasia, but early dialysis and renal transplant may still be required.[105] Other situations may be considered for prenatal intervention on an individual basis, such as obstruction of a solitary kidney,[107] although these situations are incredibly rare.

A single-center review of 18 patients with a mean follow-up of 5.8 years revealed that 6 patients (33%) required renal transplantation, 4 (22%) had renal insufficiency, and 8 (45%) had normal renal function.[88] Three patients (16.5%) required catheterization as an adjunct to voiding, and three more as the sole means of bladder emptying. Pulmonary and musculoskeletal issues persisted in 45% and 50%, respectively. Quality of life measures were not statistically different compared with a healthy population, but numbers were small and CIs were wide.

A multicenter registry was attempted in the past, but only a small number of patients were entered and long-term follow-up was not obtained.[108] Ultimately, multicenter endeavors, such as the North American Fetal Therapy Network (NAFTNet), will be required to answer many of the unanswered questions concerning appropriateness of intervention. A survey of practicing pediatric urologists confirmed that few recommend prenatal intervention. When it is considered, the strict criteria outlined above should be followed.[109] Ideally, intervention should occur before any renal injury occurs. This approach will only happen if future studies can accurately identify obstruction very early in the prenatal period, which is currently rarely accomplished.

Postnatal Evaluation and Management of PUV and Ureterovesical Anomalies

The cause of LUTO is now commonly diagnosed presumptively in the antenatal period. Previously, infants presented with failure to thrive, an abdominal mass, or urosepsis.[110] Common antenatal ultrasound findings include a distended thick-walled bladder, bilateral hydronephrosis, and oligohydramnios in some cases.[110–112] Fetal MRI can provide increased anatomic detail and possibly prognostic information, such as the quality of renal parenchyma.[12–16,113] Normal prenatal imaging and wet diapers do not exclude the possibility of LUTO in the neonatal period,[114] and suspicion should remain high when clinical signs, such as distended abdomen or urinary tract infection (UTI), are present. Normal voiding cystourethrogram also does not exclude the presence of valves, as 30% of patients with valves have normal findings.[115] While the outcomes of patients diagnosed earlier may be worse than those diagnosed later, this is indicative of a greater severity of disease and should not be taken to mean that antenatal diagnoses will not improve outcome in these patients.[116,117]

There is significant variability in the treatment of infants with PUV. Appropriate treatment is usually determined based on the overall medical condition of the infant, including renal function, hydrational status, presence of infection and lung maturity, and caliber of the urethra.

TABLE 6.2 Fetal urine electrolytes predicting renal function based on final of three or four serial bladder aspirates

	Good prognosis	Poor prognosis
Sodium	<90 mmol/L	>100 mmol/L
Chloride	<80 mmol/L	>90 mmol/L
Osmolality	<180 mOsm/L	>200 mOsm/L
Calcium	<7 mg/dL	>8 mg/dL
Total protein	<20 mg/dL	>40 mg/dL
β_2-Microglobulin	<6 mg/L	>10 mg/L

In general, some basic tenets are applicable to most cases. Catheter drainage of the bladder will allow decompression of the urinary tract, and prophylactic antibiotics should be initiated at birth. Circumcision may reduce the risk of breakthrough UTIs when reflux is present.[109,118] Initial measures of renal function are reflective of the mother's kidney function; therefore, catheter drainage should be maintained until the nadir creatinine is reached.[119–123] If the creatinine falls below 1 mg/dL, valve ablation with pediatric endoscopic equipment should be performed, after which careful monitoring of renal function, bladder function, and reflux should be continued while the child remains on antibiotic prophylaxis.[123–125] Early use of anticholinergics in children with increased voiding pressures and reduced bladder capacity may improve bladder function after primary ablation.[126]

Infants whose renal function does not substantially improve pose a much more difficult management problem. In these patients, minimizing intrarenal pressure may have a positive effect on renal function. These patients may have either low or high urinary diversion.[119,120,123,127,128] While upper tract diversion was commonly used in the past, vesicostomy is usually the initial step to decompress these kidneys. Primary vesicostomy and upper tract diversion do not appear to have an adverse effect on bladder function compared with primary ablation.[129,130] Consideration of upper tract diversion may be given in severe cases in order to minimize intrapelvic pressures and in those with urinary infection, as this optimizes renal drainage. However, little evidence exists that upper tract diversion really helps, unless infection has been present, and it complicates subsequent reconstruction. The long-term outcome in these patients depends essentially on the degree of renal damage and on bladder function.[116,131] Older children may require anticholinergics and/or bladder augmentation for the "valve bladder" if high storage pressures are demonstrated on urodynamics. Reimplantation to correct reflux may be necessary. Renal insufficiency and end-stage renal disease requiring dialysis or transplant develop in approximately 35% and 15%, respectively, with a nadir creatinine of less than 1 mg/dL having the most predictive value for adequate renal function.[132] Data are limited, but recent research on long-term sexual function of patients with PUV shows rates of erectile and ejaculatory disturbances and infertility similar to those of the general population; however, rates may be higher in patients with cryptorchidism or uremia.[133,134]

An ectopic ureterocele can present as an obstructing lesion at the bladder neck. This condition occurs with a female prevalence of approximately 3–4:1.[80,136,137] Prenatal ultrasound has detected cases in which the ureterocele creates a ball valve obstructive and cases of bilateral ureteroceles.[80] Prenatal and postnatal MRI have been used increasingly in the diagnosis of ureteroceles if ultrasound is inconclusive.[138,139] In general, these patients are managed initially by transurethral incision or puncture (Figure 6.30).[140–146] Puncture techniques have been gaining popularity after many reports of reduced rates of iatrogenic vesicoureteral reflux (VUR) compared with incision,[145,146] but numbers are still small to make definitive conclusions. Once stabilized, they undergo final management, which may include treatment of reflux, excision of the ureterocele, and in some cases, upper-pole nephrectomy and ureterectomy.[136] In general, the recent trend has been toward less aggressive management of ureteroceles and associated abnormalities.[147] Many cases of nonobstructed ureteroceles or those associated with nonfunctioning renal units have been managed nonoperatively with good results.[148,149] Associated VUR has also been shown to resolve in many instances. Infection is another indication for ureterocele incision or puncture. As in all cases of LUTO, treatment of long-term bladder dysfunction may be required.

VUR can be the cause of the upper tract dilation in as many as 35% of children with antenatal hydronephrosis.[109] Recent reviews suggest that this is less likely in African Americans and more common in males than females,[150,151] but all should be screened. Children with dilated upper tracts should have a voiding cystourethrography (VCUG) to rule out reflux prior to treatment for other urinary tract abnormalities.[152] The recent American Urologic Association (AUA) guidelines on VUR highlight the need to evaluate and treat associated bowel and bladder dysfunction (BBD) when feasible, preferentially before surgical intervention for VUR. Continuous antibiotic prophylaxis (CAP) is indicated for children less than 1 year in age with a history of febrile UTI, or high-grade (III–V) reflux, and optional for those with lower grades of reflux without febrile UTIs. Circumcision should be offered as an option to any male neonate with VUR, as it may decrease risk from UTIs.[153]

NEURAL TUBE DEFECTS

Although not primarily a urologic abnormality, neural tube defects, including open defects (meningomyelocele) and closed defects (lipomeningocele and sacral agenesis), result in significant urinary tract morbidity. The timing of neurosurgical repair differs for each based on the likelihood of complications as follows: meningomyelocele, prenatally and immediately postnatal; lipomeningocele, within the first year; and sacral agenesis, as symptoms dictate.

The use of folic acid supplementation and the termination of affected fetuses led to a significant decrease in the birth rate of children with myelomeningocele, which has since stabilized at 3.4 per 10,000 live births.[62,154–158] The Public Health Service of the United States currently recommends that all women capable of childbearing consume 0.4 mg of folic acid per day and pregnant women consume 0.6 mg per day to decrease the risk of neural tube defects and anencephaly.[159] There is a slight increase in the incidence of myelodysplasia if other family members also have the condition.[160,161]

Meningomyelocele

The accurate diagnosis of open neural tube defects during the prenatal period is achievable in nearly all cases by a combination of routine screening of maternal serum α-fetoprotein and targeted sonography.[162,163] For prognostic purposes, prenatal ultrasound is able to predict the level of the spinal cord lesion within one and two levels in 78% and 96% of cases, respectively, for open spinal cord

defects with improved accuracy and tertiary centers.[52] Neuropathic bladder effects have been detected before birth.[164,165]

There is evidence of progressive neurologic deterioration during gestation, likely from continued exposure of the spinal cord to amniotic fluid and trauma during birth.[166–169] These findings, combined with promising early results from animal and human studies on prenatal intervention, led to a large-scale randomized controlled trial of prenatal versus postnatal intervention.

The Management of Myelomeningocele Study (MOMS) halted accrual early at 183 of the planned 200 patients due to early demonstration of efficacy.[170] Prenatal intervention showed reduced rates of infants meeting criteria for ventriculoperitoneal shunt placement (65% vs. 92%) and reduced hindbrain herniation. Overall functional outcome scores were also significantly higher in the prenatal intervention group. The prenatal group also had a significantly higher rate of preterm birth, intraoperative complications, uterine scar defects, and maternal transfusion. Those receiving prenatal intervention also had a higher rate of subsequent surgery for a tethered cord (8% vs. 1%). Prenatal myelomeningocele repair will likely soon be routinely offered at fetal centers around the United States.[171]

High-quality data from MOMS on bladder function is currently unavailable, but short-term follow-up and retrospective data from earlier studies have not shown any urologic benefit to prenatal intervention compared with postnatal intervention. The durability of prenatal intervention is also still unknown. The urologic care of these patients does not significantly differ from those treated in the postnatal period[172] and requires close follow-up based on urodynamic studies.

Open myelomeningoceles (Figure 6.25) are readily identifiable at birth. The level of the lesion does not correlate with the neurologic defect because some nerve roots may be left intact. An Arnold–Chiari malformation can affect the brainstem and pontine micturition center. It is this malformation that is most likely to be prevented by fetal surgery. Tethering of the spinal cord and different growth rates in the distorted vertebral bodies can affect the final neurologic deficit.[173] Likewise, immediately after birth and during infancy and early childhood, a changing pattern is often seen in the urodynamics of these patients.[174–176] It is impossible to make broad generalizations, but in children with high thoracic lesions, patients may have an intact sacral reflex arc. Those with lesions at S1 and below can have normal bladder function, but upper or lower motor lesions involving the bladder and/or pelvic floor are also seen.

Surgical closure of the spinal defect does not equal a cure from urologic sequelae. Comparison of postvoid residuals actually found higher values in the immediate postsurgical period, likely from spinal shock.[177] Although a less invasive approach is favored by some in hopes of avoiding unnecessary catheterization and urodynamic testing, a proactive approach, including early initiation of clean intermittent catheterization (CIC), prophylactic antibiotics in any child with hydronephrosis, and full urologic workup, including renal sonography, VCUG, and urodynamics, yields important prognostic information and has been shown to protect both upper and lower tract systems.[174,178–186]

Initial management usually involves initiation of CIC every 4–6 hours in all children that is continued after surgery. Frequency may be reduced if postvoid residuals decrease or CIC stopped all together if no urine is found when catheterizing, but it is important for all parents to learn CIC during the initial hospitalization to be used if needed. Prophylactic antibiotics are started in any child with evidence of reflux. Circumcision may be considered for male patients, as it has been shown to decrease the risk of UTIs in patients with reflux.[109] Use of the Credé maneuver should be avoided. Urodynamics are typically performed after surgical spinal closure by around age 6 weeks, and anticholinergic medication is started if excessive uninhibited bladder contractions are present. The dynamic nature of this disease requires routine surveillance throughout the patient's life, but particularly during periods of rapid linear growth, when spinal cord tethering may occur.[184,187]

Lipomeningocele

This abnormality is difficult to identify on physical examination, but the vast majority of children with lipomeningocele have an identifiable superficial or cutaneous lesion. A high level of suspicion and careful examination of the lower spine will help detect the disease early, which is particularly important, as recent research suggests that those surgically repaired by 1 year of age have better long-term urologic outcomes than those repaired later.[188] Prenatal detection, although exceedingly rare,[189] would allow earlier intervention and likely improve outcomes.

The neurologic changes occur because of an intradural lipoma. This lesion results in a broad spectrum of disease and presentation.[190] Typically, during early childhood, there are few outward physical abnormalities, and only with complete urodynamic assessment is the effect on the bladder identified.[191] The most common urodynamic findings are consistent with an upper motor neuron lesion. Sphincter dyssynergy is less often identified in this group. In older children where the diagnosis has been delayed, there are often neurologic changes in the lower extremities.[192] The bladder changes in the older group are mixed between detrusor hyperreflexia and detrusor areflexia. The best methods to identify and characterize these lesions are MRI and complete urodynamic assessment.[193]

Sacral Agenesis

This lesion is even more difficult to identify on physical examination, and often the patient presents at an older age with failure to become continent.[194–196] Loss of the lower vertebral bodies can be easily seen on a lateral lower plain film of the spine or on MRI. White and Klauber suggested that palpation of the coccyx could identify absent vertebral bodies, but radiographic confirmation is the best method.[197] These patients have a stable neurologic lesion that does not progress with growth. However, the results of urodynamic studies are variable.[196,198] Patients may have no sign of denervation or hyperreflexia, areflexia, intact sphincter function, or sphincter dyssynergy, and

some have absent control over the sphincter.[199] A high level of suspicion and complete urodynamics help to guide treatment, with specific intervention based on the identified findings.[194–196]

DISORDERS OF SEX DIFFERENTIATION

The identification of disorders of sex differentiation (DSDs), formerly referred to as intersex disorders, in the prenatal period is the result of better screening techniques and advances in the understanding of the inheritance of these diseases. Unlike the postnatal period, where the discovery of ambiguous genitalia is the initiating factor, amniocentesis, CVS, and improved sonographic techniques allow prenatal identification of many cases of DSDs.[200–205] The prenatal identification of these problems results in the need to provide adequate prenatal counseling.[206,207] Regardless of the timing of identification, complex medical, social, and psychological aspects of a new diagnosis of DSD, although medically speaking not an emergency, do need to be handled with sensitivity and immediacy to optimize long-term outcomes. A multidisciplinary approach by an experienced team, including a pediatric urologist, endocrinologist, geneticist, and psychiatrist or psychologist, is best. In most instances, sexual assignment is straightforward, and where it is not, consideration should be given to delaying the decision to intervene surgically until the infant is older[208,209] (see Chapter 29). The nomenclature for DSDs underwent a substantial revision in 2005.[210] A large panel made up of medical and lay experts devised a new system that classified DSDs based on chromosomal genotype and physical attributes. Terms assigning a specific gender or carrying any negative connotations were avoided. Specifically, terms such as *intersex*, *male*, *female*, *hermaphrodite*, or *pseudohermaphrodite* were replaced with conditions such as 46,XX DSD, 46,XY DSD, and sex chromosome DSD.

CAH, in particular, has been a model for prenatal pharmacotherapy. Identifying CAH before birth provides the opportunity to treat the fetus in the hope of preventing androgen effects on fetal development, although therapy is still most effective based on known familial risk rather than a confirmed diagnosis.[211–219] CAH is the most common cause of ambiguous genitalia at birth and of 46,XX DSD. It is the only form of DSDs that can be life threatening.

The worldwide incidence of CAH is estimated at 1 in 15,000 live births, with significant ethnic variation.[220] Classic CAH, a deficiency of the 21-hydroxylase (21-OH) enzyme, accounts for 95% of cases of CAH and is the most severe form.[217] Other enzyme deficiencies and associated genes are shown in Table 6.3. The 21-OH enzyme is part of the cytochrome p450 enzyme family and is encoded by the *CYP21A2* gene located on the short arm of chromosome 6.[214] Deficiency of 21-OH results in the inability to synthesize cortisol. The pituitary and hypothalamus overstimulate the adrenal gland, causing the overproduction of androstenedione. The androstenedione is further metabolized, predominantly to testosterone and dihydrotestosterone (DHT), resulting in the prenatal virilization of the female fetus. A variety of identified deletions and point mutations of the *CYP21A2* gene lead to a spectrum of severity in classic CAH, with 75% experiencing the congenital salt-wasting (SW) form of the disease and the remaining 25% with the simple virilizing (SV) form.[171,215,217] Both SW and SV forms are associated with a range of external genital virilization. It is this virilization that is the target of prenatal therapy (Figure 6.29).

TABLE 6.3 Possible enzyme deficiencies and associated genes in CAH

Early treatment with dexamethasone can prevent or minimize severe genital abnormalities in some patients.[214,218,221–223] A recent meta-analysis demonstrated an overall reduction in virilization measured by a Prader score of –2.3 (95% CI –3.4 to –1.3) for fetuses treated with maternal dexamethosone,[218] although the overall data quality was low, based mainly on observational studies. Despite the known beneficial effect of prenatal treatment of affected female fetuses with CAH, there is continued controversy, which exemplifies that of many prenatal treatments.[224–227]

The current controversy is in large part due to the time disparity between the accurate diagnosis of CAH and the ideal initiation of therapy. Adrenal steroidogenesis begins in the fetus during gestation weeks 6–7, and external genital differentiation takes place during weeks 7–12. Prenatal treatment of CAH should start before week 6 or 7 to completely prevent androgenic effects; however, a diagnosis of CAH depends on invasive CVS to obtain fetal DNA that cannot be done until 9–12 weeks' gestation. Treatment (20 μg/kg/day of oral dexamethasone divided into three daily doses) is therefore begun as soon as pregnancy is confirmed in all at-risk fetuses, which are defined by a diagnosis of CAH in an earlier pregnancy. Since CAH is inherited in an autosomal recessive manner, the risk of having a female infant with classic CAH for any pregnancy by two parents with a previously affected child is one in eight. Males do not need to be treated since excess androgens do not harm their fetal development. This means that seven fetuses are treated unnecessarily for every one female with CAH that benefits from treatment.

Newer noninvasive methods to differentiate fetal sex based on detection of cell-free fetal DNA (cffDNA) in maternal serum have been able to identify male fetuses as early as 7 weeks' gestation and accurately determine fetal sex as early as 8 weeks.[228] This technology has yet to reach clinical practice.

Maternal dexamethasone has been shown to be overall well tolerated, although edema, striae, and weight gain are more prevalent, while there is insufficient evidence of serious complications, including hypertension and gestational

diabetes.[218,229] Long-term effects to the children born to mothers receiving dexamethasone are incompletely understood, but there is some concern for increased incidence of social anxiety or difficulty with specific learning skills.[219] The fetal metabolism of dexamethasone is not understood, and the doses recommended for treatment are greater than required to suppress the adrenal in the adult.[224]

These concerns are apparent in the clinical guideline on CAH published by the Endocrine Society in 2009. The clinical guideline on CAH recommends that prenatal treatment of CAH be considered experimental and conducted as part of institutional review board investigations when possible.[227] No specific protocols were issued. The promise for future widespread clinical application lies in more robust prospective data on all aspects of prenatal steroid therapy, combined with the ability to predict who will benefit from treatment as early as possible.

Most cases of DSDs other than CAH are identified inadvertently.[204,230] In some cases, this is the result of an amniocentesis because of a simple parental request to know the sex of the fetus. In other cases, there can be an issue of other known inheritable diseases, such as determining the likelihood of an X-linked disorder (e.g., hemophilia). Knowing the sex may be helpful in confirming the cause of a structural disorder (e.g., PUV) that does not occur in girls. In cases with a family history of CAH, genetic sampling can identify the inherited genetic disorder. The identification of DSD may also result from routine screening of an older mother. In situations where the genetic sex is known, but the genital screening by ultrasound does not appear to match the genotype, clinicians should consider the possibility of DSD. In the case of a 46,XY karyotype with female-appearing genitalia, the differential diagnosis should include gonadal dysgenesis or androgen insensitivity. In severely androgenized females with CAH, a 46,XX karyotype may be associated with ultrasound findings suggesting male genitalia. Table 6.4 lists the chromosomal analyses and possible DSDs.

Postnatal Evaluation of Disorders of Sex Differentiation

The postnatal consultation for ambiguous genitalia is one of the urgent problems that a urologist must face. The initial approach to managing DSD patients is to identify and treat possible life-threatening abnormalities.[208,231,232] Although CAH is the most common form of DSDs resulting in ambiguous genitalia at birth, it is important to have a diagnostic plan for evaluating all patients. A practical algorithm using the new DSD terminology based on history, chromosome determination, serum tests, screening radiological studies, and pathology was published by Lambert et al.[30] and is used by the authors (Figure 6.4).

TABLE 6.4 Chromosomal analyses and possible disorder of sexual development

46,XX	CAH Maternal virilizing syndrome Ovotesticular DSD Gonadal dysgenesis
46,XY	5α-Reductase deficiency Androgen insensitivity syndrome Dysgenetic testes Primary testicular failure Leydig cell failure Persistent Müllerian duct syndrome
46,XX/XY	Ovotesticular DSD
45,X, 45,X/46,XX, 45,X/46,XY, etc.	Ovotesticular DSD Gonadal dysgenesis (pure or partial)

The initial history should focus on degree of prematurity, family history (urologic abnormalities, perinatal deaths, precocious puberty, amenorrhea, etc.), and drug ingestion history (oral contraception during pregnancy or hormones for assisted reproductive techniques). One may note virilization or a cushingoid appearance of the mother, and review of prenatal tests, such as sonography or karyotype, may be helpful.

Physical examination and screening laboratory studies facilitate the differential diagnosis relatively rapidly. Female infants with CAH will have varying degrees of virilization, from hypertrophy of the clitoris and mild labioscrotal development to a normal-appearing male phallus and scrotum. Palpation of the gonads suggests a differential diagnosis. If no gonads can be palpated with ambiguous or masculinized genitalia, all forms of DSDs are possible, with 46,XX being the most common. When only one gonad is palpable, one should consider 45,X/46,XY DSD, ovotesticular DSD, and 46,XY DSD. When both gonads are palpated, 46,XY DSD and rarely ovotesticular DSD are typically diagnosed.

The next step involves targeted laboratory and radiologic screening. Initial evaluation should include measuring serum electrolyte, 17-hydroxyprogesterone, testosterone, DHT, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Radiologic evaluation consists of pelvic sonography and VCUG. When 17-hydroxyprogesterone is elevated, the karyotype is 46,XX, and a uterus is identified by ultrasound, one is dealing with CAH. Checking the 11-deoxycortisol levels can differentiate between 21α-hydroxylase and 11β-hydroxylase deficiency. If 11-deoxycortisol levels are low, then 21α-hydroxylase deficiency is confirmed, where as 11β-hydroxylase deficiency will show elevated 11-deoxycortisol.

If the 17-hydroxyprogesterone levels are normal and a uterus and ovaries are identified in a child with a 46,XX karyotype, a maternal virilizing syndrome should be considered the cause of the 46,XX DSD.

A combination of imaging findings and laparoscopy with or without biopsy is often required to make a definitive diagnosis in patients without CAH as the cause of the ambiguous genitalia. Sonography is only 50% accurate in locating abdominal testicles,[233] but it can typically identify inguinal testicles and assess Müllerian structures. If ultrasound proves inadequate, MRI or a fluoroscopic genitogram may provide additional valuable information. Open or laparoscopic exploration with biopsy is required when testes are nonpalpable or intra-abdominal. When biopsy identifies a streak gonad, one should consider gonadal dysgenesis, which is pure when both gonads are represented as streaks (45,X, 45,X/46,XX, 46,XX, and 45,X/46,XY) or partial when one streak gonad and one testis are present (45,X/46,XY and 46,XY). In cases with both a testis

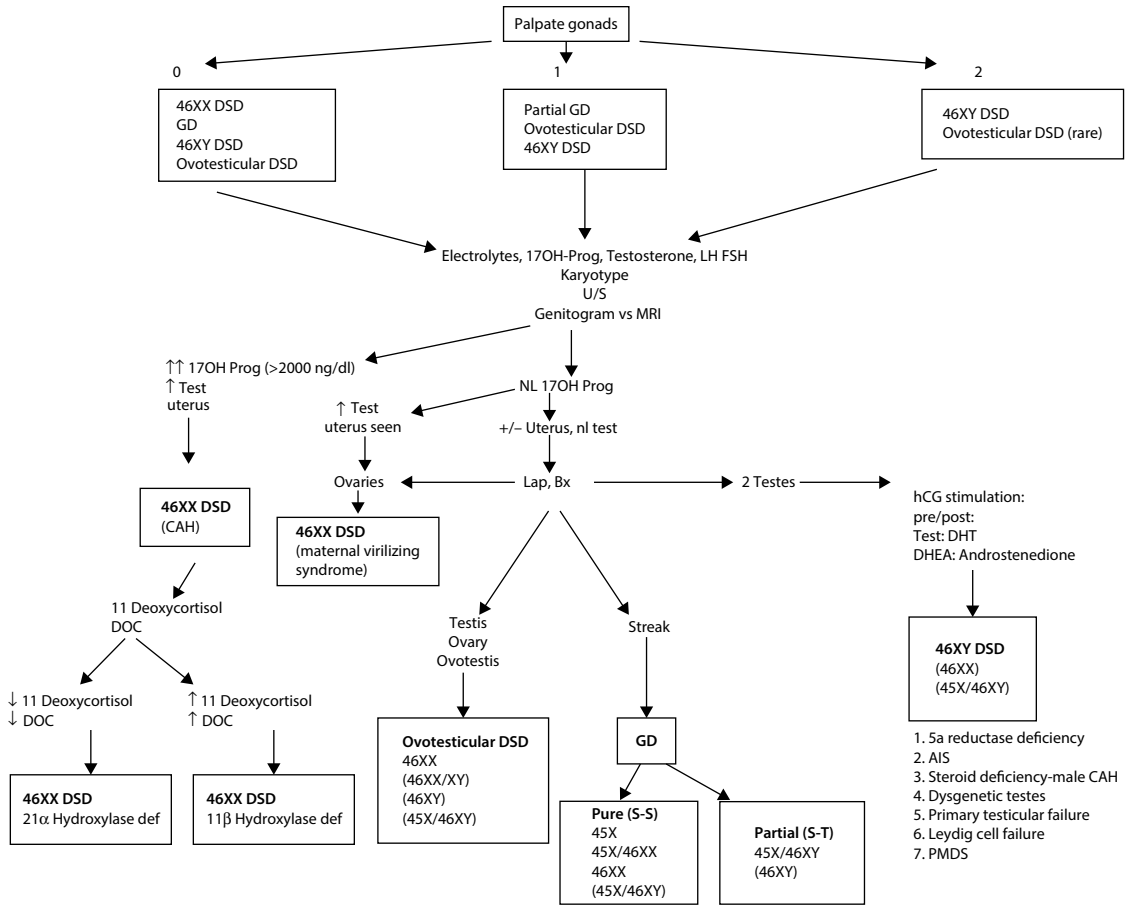

FIGURE 6.4 Anatomic and endocrine approach to DSD evaluation. NL, normal; S, streak gonad; T, testis. (Adapted from Lambert SM et al. *Urol Clin North Am* 2010;37(2):195–205.)

and ovary or two ovotestes, one should consider ovotesticular DSD (46,XX, 46,XX/XY, and 46,XY). If two testes are identified, an hCG stimulation test should be performed. Serum testosterone, DHT, dehydroepiandrosterone (DHEA), and androstenedione should be measured before and after stimulation. This will identify the cause of the 46,XY DSD. A testosterone-to-DHT ratio of greater than 20 suggests 5-α-reductase deficiency. Other causes of 46,XY DSD include testicular failure, dysgenetic testes, steroid deficiency secondary to male CAH, persistant Müllerian duct syndrome, complete androgen insensitivity syndrome, and exogenous influences.

Karyotyping should be performed even if prenatal chromosomal studies from amniocentesis have been done. In cases of CAH, the Barr body is positive. Urinalysis should be performed. Screening sonography and genitography in appropriate situations are helpful in the evaluation, in order to identify ovaries and a uterus.

Initial treatment involves glucocorticoid and mineralocorticoid replacement. It is strongly recommended that these patients be reared as female because of the chromosomal sex and potential fertility, but in the most virilized form, questions have arisen as to the best sex of rearing.[209,234,235]

Initial genetic testing includes metaphasic karyotyping of chromosomes. Interphasic fluorescent in situ hybridization (FISH) can be used for more detailed analysis of the sex chromosomes or mosaicism. Genes associated with many causes of DSDs, such as CAH and complete androgen insensitivity, are now known and can be sequenced to determine a patient's specific mutation. Genetic sequencing is best carried out at a later date when history, physical exam, and preliminary tests have narrowed the diagnosis. Input from genetic counselors is essential so that parents understand the implications for themselves, the patient, and current and future siblings.

ABDOMINAL MASSES

The prenatal identification of a solid mass seldom requires early intervention but often generates an urgent consultation. The neonate presenting with an abdominal mass is of particular importance to the pediatric urologist because the majority of such lesions arise in the retroperitoneum in general and the kidney specifically.[236–239] Traditionally, they presented with a palpable mass. Although some still present this way, masses are far more likely to be detected by prenatal sonography. At the time of presentation to the urologist, most have already been categorized as solid, cystic, or hydronephrotic. The urologist must be familiar with

the masses that originate from the genitourinary tract, as well as the following broad spectrum of other potential etiologies:

1. Hydronephrosis and renal cysts
   a. Nonobstructive hydronephrosis
   b. Ureteropelvic junction (UPJ) obstruction
   c. Unilateral cysts (multicystic dysplastic kidney [MCDK] and multilocular cystic nephroma)
   d. Bilateral cysts (autosomal recessive and autosomal dominant polycystic kidney disease [ADPKD])
2. Midline cystic abdominal masses
   a. Hydrometrocolpos
   b. Ovarian cyst
   c. Distended bladder
   d. Urinary ascites
3. Solid abdominal masses
   a. Neuroblastoma
   b. Sacrococcygeal teratoma
   c. Congenital mesoblastic nephroma
   d. Wilms' tumor, rhabdoid tumor, clear cell sarcoma, angiomyolipoma, and ossifying tumor of the kidney
   e. Renal vein thrombosis (RVT)
   f. Renal artery thrombosis
   g. Adrenal hemorrhage
   h. Rhabdomyosarcoma
   i. Germ cell tumor

Figure 7.16 provides a flow diagram that outlines the general framework used to evaluate the lesions identified antenatally. The evaluation of an infant with a mass often becomes a continuation of the evaluation that began prenatally. Ultrasound, plain films, computed tomography (CT) scans, and MRI all have important roles in the imaging of pediatric abdominal masses.[238,240,241] It is important to note that neonates with masses represent a diagnostic emergency for both the parent and the referring physician, but rarely do they require emergency surgery, and prenatal intervention is almost never indicated.

Hydronephrosis and Renal Cystic Lesions

UPJ obstruction causing hydronephrosis remains one of the most common causes of an abdominal mass in the neonate.[242,243] The diagnosis is almost always made by prenatal ultrasound.[238,244] Significant hydronephrosis has an incidence of approximately 1:600 infants; however, hydronephrosis causing an abdominal mass is much less common.[245] Barring the development of oligodramnios or anhydramnios, most fetuses are observed until term delivery. UPJ obstruction is usually unilateral but can be bilateral in up to 20%–40% of cases.[246,247]

Postnatal management includes prophylactic antibiotics and postnatal sonography. Waiting 48 hours after birth to perform ultrasound examination is often recommended to minimize the incidence of false-negative studies,[248] although the data suggest that this traditional delay is unnecessary.[249] Clearly in the face of a neonate with a mass, no delay is warranted. If hydronephrosis is detected and no ureter is visualized, the presumed diagnosis of UPJ is made. A VCUG will exclude the possibility of ipsilateral or contralateral reflux. This test should be performed before any intervention is considered. To establish the diagnosis, a well-tempered renogram is performed. When performing lasix renograms, it is important to optimize the study by following an accepted protocol and ensuring that the infant is well hydrated.[250–252] Prophylactic antibiotics are discontinued when reflux and obstruction are excluded.

In cases where it is believed that the obstructed kidney may have minimal function, proceeding with evaluation and treatment earlier is often indicated because the neonatal kidney has significant ability to regain function.[253] When presentation involves an abdominal mass from massive hydronephrosis, evaluation of the viable renal parenchyma is difficult. In these cases, a period of percutaneous drainage, followed by nuclear scintigraphy to evaluate function, may reveal a salvageable renal unit. A biopsy at the time of surgical correction has the best predictive value with regard to future renal function (Figure 6.5).[254] If no function is present on the renal scan, the diagnosis of MCDK must be considered.

Surgical treatment of UPJ obstruction will be required in approximately 20% of the cases and depends on the degree of obstruction and whether the lesion is unilateral or bilateral.[248,255] Clearly, children with significant bilateral obstruction require early intervention. Since surgical repair of UPJ in infants does not have a higher complication rate than in larger children, age does not affect the decision to intervene surgically.[256]

Increasingly, cystic renal lesions in the neonatal period are detected antenatally by sonography. In evaluating these lesions, it is useful to divide them into unilateral and bilateral categories. This allows a natural division of diagnostic possibilities.[257] Most lesions are detected antenatally but do not require intervention or further evaluation until after birth.

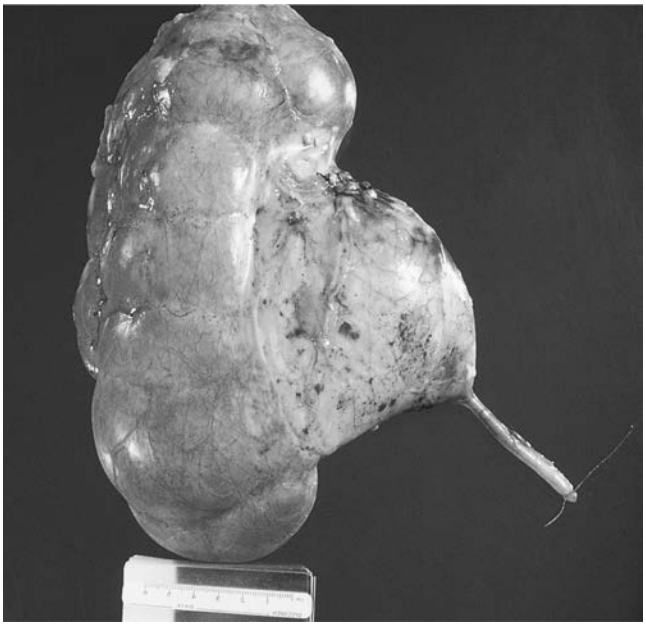

FIGURE 6.5 End-stage UPJ obstruction showing how the dilated calyces can mimic cystic structures.

Unilateral Cystic Lesions

With an overall incidence of 1 in 4300, MCDK is the second most common cause of an abdominal mass in infants.[258,259] Usually, the mass is unilateral and may be palpable as a multilobular "cluster of grapes" that transilluminates. These lesions may be quite large and can impede normal feeding because of compression of the stomach; alternatively, they may impinge on the diaphragm and affect respiration. Importantly, this lesion has a high incidence of associated contralateral renal abnormalities. Contralateral lesions are seen in 25%–31% of these children.[259–261] The two most common kidney lesions are UPJ obstruction and contralateral VUR. Miller et al. recently reported an incidence of contralateral VUR of 26.4%. The majority (89%) of the VUR was low grade (I or II). The majority of the cases underwent spontaneous resolution.[262] While ultrasound evaluation of the contralateral kidney should be performed, the need for a VCUG in cases of where the contralateral kidney is normal by sonography is controversial.

Diagnosis of MCDK is usually made postnatally with a sonogram, which shows a multiloculated mass with little parenchyma (Figure 6.6). The cysts are generally nonconnected. When the cysts appear to be connected, the diagnosis of severe UPJ obstruction should be entertained. Although there are reports of familial lesions, most are sporadic and familial screening in the absence of a significant familial history is not warranted.[263] The diagnosis is confirmed with a dimercaptosuccinic acid (DMSA) scan that demonstrates no function of the affected side. Contralateral imaging with sonography to rule out obstruction or bilateral MCDK is mandatory. Ureteral atresia is associated with a higher incidence of contralateral abnormalities than is renal pelvic atresia.[264]

While previously nephrectomy was commonly performed, today serial sonography is the standard. Multicystic kidneys typically regress.[265–267] Factors predicting resolution are still under investigation. Potential predictors of resolution are right-sided lesion and initial size of <62 mm.[268,269] Rare reports of malignancy have led some to suggest that these lesions should be removed if they persist, and only lesions that involute be managed nonoperatively.[270,271] More recently, it is recognized that the likelihood of malignancy is extremely rare.[272,273] Rarely, lesions that compromise respiration or feeding or are associated with hypertension should also be excised.[274]

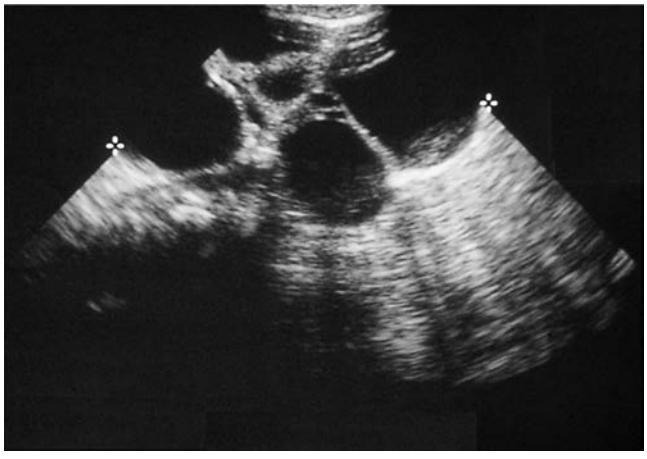

FIGURE 6.6 Sonogram of multicystic dysplastic kidney. (From Anthony Balcom, Milwaukee, WI. With permission.)

Multilocular cystic nephroma is a rare benign renal neoplasm. Lesions may be unilateral or bilateral, and bilateral metachronous lesions have been reported.[275,276] A familial association has been reported, and partial nephrectomy is being increasingly used when feasible to preserve renal parenchyma (Figure 6.7).[277,278]

Bilateral Cystic Lesions

Autosomal recessive polycystic kidney disease (ARPKD) is an inherited nephropathy with an overall incidence of approximately 1:20,000 and presents with varying degrees of severity.[279–281] Children present with massively enlarged kidneys that are typically seen on antenatal or postnatal sonograms as homogeneously hyperechogenic. In severe cases, oligohydramnios and Potter's facies may be present. The sonographic pattern is sufficiently different from that of MCDK and ADPKD to distinguish reliably between them. Pathologically, the kidneys of these children exhibit ectasia and cystic dilation of the collecting tubules. Associated conditions include pulmonary hypoplasia and hepatic fibrosis, both of which contribute significantly to morbidity. *Abnormalities of the ARPKD gene*, PKHD1, *are responsible for this disease*. Prognosis for these children depends on the spectrum of their disease, but is generally poor, with those surviving the neonatal period requiring hemodyalysis and transplantation.[282] Up to 30% of children die as neonates, with 20%–45% progressing to end-stage renal disease by age 15.[280,283] Improvements in renal replacement therapy have led to an 80% 10-year survival rate for those who survive the neonatal period, and liver disease may have the largest impact on long-term morbidity and mortality.[280,284]

*ADPKD has an incidence of 1 in 500 to 1 in 1000 births, and two gene sequences on chromosome 16 (*PKD1*) and chromosome 4 (*PKD2*) have been associated with this disorder.*[285,286] *PKD1* accounts for 64%–85% of cases and produces a more severe disease state with an earlier onset.[287,288] The proportion of *PKD2*-associated disease has increased in recent studies to 36%, likely due to increased detection of this less severe form by imaging.[288] A third locus, *PKD3*, has been proposed but remains unidentified.[281,287] While formally called "adult" polycystic kidney disease, this name is inaccurate, as 2%–5% of cases present in childhood or in utero.[281] Patients with this disease may be diagnosed by prenatal sonogram. Sonography is also the primary modality used to screen potentially affected siblings.[281,289] Infants born with this disorder often have massive renomegaly, and severely affected infants have poor survival. It is important to remember that in children, the disease may initially present unilaterally or with asymmetry. A meta-analysis of the cases identified in utero revealed that 43% of cases died before the first year of life and a significant proportion (67%) developed hypertention by age 3.[290] Children who do not present in the neonatal period often come to attention later in life with hypertension, impaired renal function, proteinuria, or hematuria. Associated conditions include hepatic and pancreatic cysts, as well as cerebral

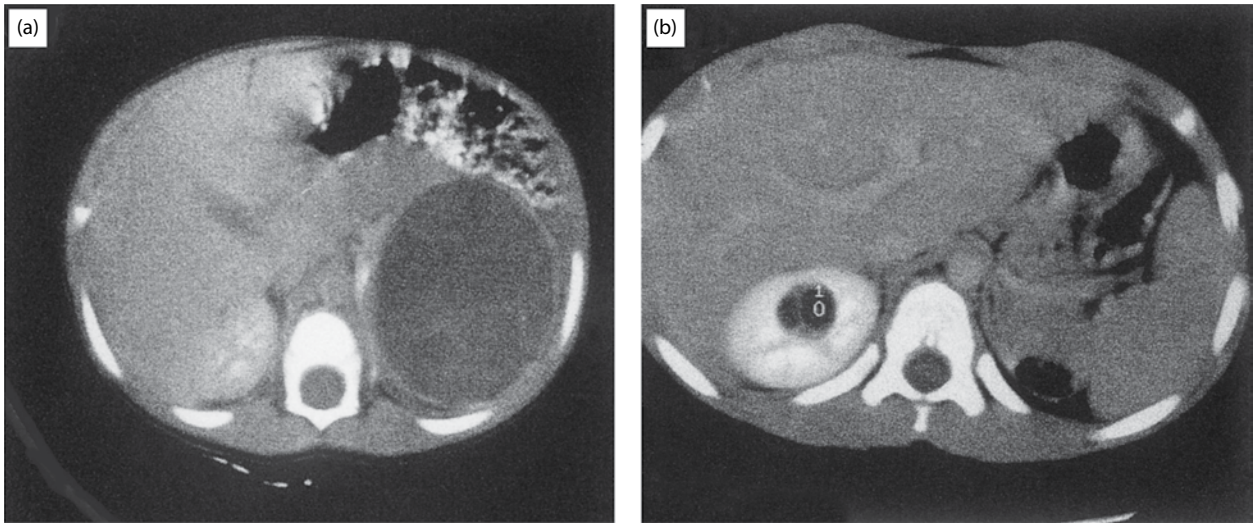

FIGURE 6.7 Multilocular cyst of the kidney (cystic nephroma). (a) CT scan of cystic nephroma in the left kidney with a normal right kidney. (b) CT scan of the same patient 2 years later with a solitary right kidney and metachronous cystic nephroma. (From Ferrer FA et al. *Urology* 1994;44:254–9. With permission.)

aneurysms. Although the outlook for these patients is improving with new targeted therapies,[291] approximately half will develop end-stage renal disease by age 60.[281,292]

Midline Cystic Abdominal Masses

As with UPJ and MCDK, modern ultrasonography has greatly facilitated the diagnosis of other less common cystic abdominal masses in infants. Previously, children would often undergo laparotomy to establish such a diagnosis.

Hydrometrocolpos refers to the distension of the vagina with mucus and blood derived from uterine and cervical glands. Produced in response to maternal estrogens, it results from vaginal obstruction secondary to imperforate hymen or other obstructive vaginal anomalies, such as transverse vaginal septum or vaginal atresia.[293,294] In patients with a mid- or high transverse septum or vaginal agenesis, a thorough search for associated genitourinary and gastrointestinal abnormalies should be performed.[295,296] It most commonly presents as a midline abdominal mass and/or an interlabial mass in the perineum, which is the bulging imperforate hymen. The diagnosis has also been made on antenatal sonography.[297–299] Careful physical examination will show that the mass is anterior to the rectum. Sonography will indicate that the lesion is behind the bladder. A common finding in these patients is LUTO and hydronephrosis.[300,301] Once the diagnosis is made, incision of the hymen and drainage result in resolution of the mass. Hydronephrosis then usually resolves with time. Care must be taken because simple percutaneous drainage may result in reaccumulation of secretions within the vagina. Serial ultrasonography should be performed to ensure that the hydronephrosis resolves. Other causes of an interlabial mass in a newborn infant include hydro(metro)colpos, prolapsed urethra, prolapsed ureterocele, and paraurethral cyst.

Ovarian cysts are the third most common cause of an intra-abdominal mass in an infant, after renal and gastrointestinal causes. They may exist in up to 30% of neonates.[302] This diagnosis has been made prenatally by ultrasound as well as postnatally.[303,304] The classic prenatal sonographic appearance is that of an anechoic, unilocolar mass in the fetal pelvis. Any internal echogenicity suggests cyst torsion or hemorrhage.[302] The majority of cysts regress and only require observation. Large cysts may compromise bowel or respiratory function. Adnexal torsion in females followed by cystic degeneration of the ovary may occur. Surgical excision of the cystic mass is typically indicated for cysts greater than 4 cm because of increased risk of torsion or heterogeneous cysts that are likely already torsed (Figure 6.8). [305]This can be accomplished by open surgery or may be achieved laparoscopically, even in infants (Figure 6.9).[306,307]

Dilation of the urinary bladder or megacystis can also result in an abdominal mass. It is most typically associated with PUVs in male infants. The classic ultrasound findings include a dilated, thickened bladder and a dilated posterior urethra ("keyhole sign"). Other potential causes include urethral atresia, megacystis–microcolon syndrome, prune

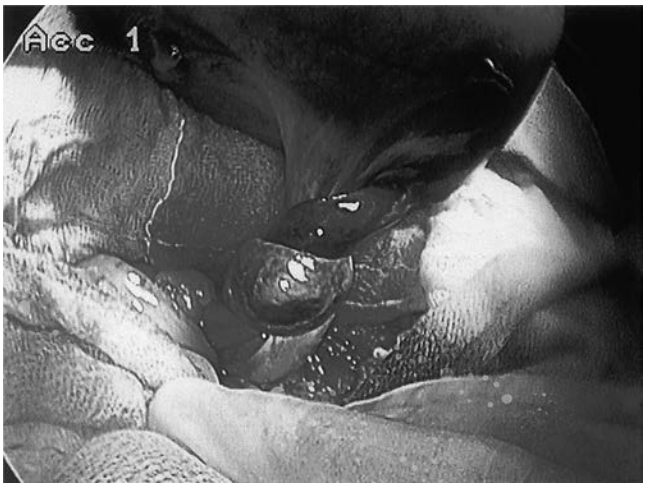

FIGURE 6.8 Torsion of the ovary presenting as a complex cyst.

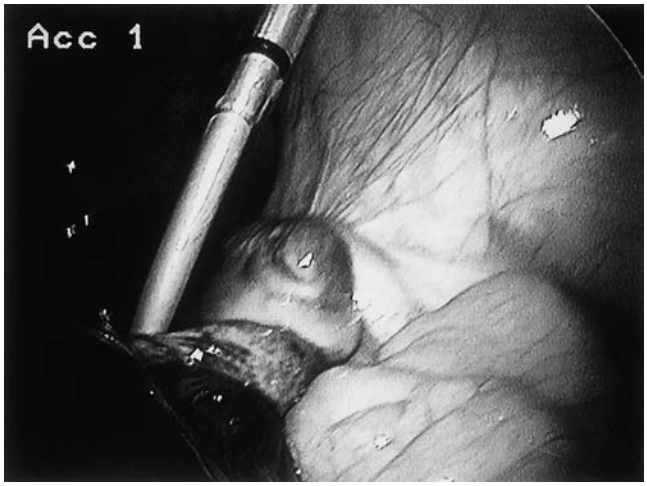

FIGURE 6.9 Laparoscopic identification of ovarian torsion.

belly syndrome, anterior urethral valves, and ureterocele obstructing the bladder outlet. Neonatal urinary ascites previously presented as an enlarged abdomen in newborns; however, today the diagnosis is frequently made in utero by antenatal sonography.[308–310]

Ascites in the fetus or newborn can be from urologic and nonurologic causes. *Urinary ascites accounts for about 30% of all cases of neonatal ascites.*[311] Among urologic causes, LUTO and trauma are most common. Specifically, PUVs, urethral stenosis, distal ureteral stenosis, anterior urethral valves, and obstructing ureteroceles have all been associated with neonatal urinary ascites (Figure 7.21).[312–317] Less frequently, obstructed and hydronephrotic kidneys may also be the cause. In these cases, extravasation of urine occurs either from the bladder or, more commonly, from a forniceal rupture in the kidney.[318] Ascites from unilateral obstructive lesions has been reported, although far less commonly than in cases of bilateral obstruction.[319,320] Alternatively, perinatal trauma to the urinary tract may also cause neonatal ascites.[321] This includes iatrogenic bladder perforation from bladder or umbilical artery catheterization.[322–324]

Sonography and VCUG can usually determine the urologic abnormality and site of extravasation in those with neonatal urinary ascites. Historically, plain film x-ray findings of a ground-glass appearance of the abdomen with floating loops of bowel have been described in patients with ascites. Neonatal urinoma, which may or may not be associated with ascites, can be identified by a "c" sign, a rim of opacified contrast around the kidney on intravenous pyelography (IVP).[325] Clinically, these patients can be quite ill. The characteristic laboratory findings include hyponatremia, hyperkalemia, and elevated serum creatinine.[326] Treatment is individualized, but urinary drainage with a urethral catheter allowing the intraperitoneal urine to be reabsorbed, along with urinary antibiotic prophylaxis, is often sufficient. Open or percutaneous drainage may be required in instances where infection of the urine occurs or when respiratory impairment is due to the mass effect. Previous reports of 70% mortality have improved to less than 15% in more recent series.[316,327–329] De Vries et al. reported the long-term follow-up of a series of patients with severe obstruction that had good lower tract and renal function.[330] Like others, the authors postulate that the development of ascites serves as a protective mechanism, allowing the kidney to decompress, minimizing damage from obstruction.[329,331–333] Nonurologic causes of neonatal ascites include erythroblastosis fetalis, cardiac or hepatic abnormalities, sepsis, and gastrointestinal perforation.[242,334]

Solid Abdominal Masses

Solid lesions in children are being detected prenatally with increasing frequency. One of the best examples is neuroblastoma.[335–337] While early detection of neuroblastoma does not necessarily change initial management, it results in the child receiving treatment sooner. In addition, patients with neuroblastomas detected early in life have a better outlook.[338,339] Thus, early diagnosis probably improves the prognosis.[335] As a rule, solid lesions detected antenatally are followed before delivery, and then after birth are imaged by CT scan or MRI. Occasionally, a postcontrast kidney, ureter, and bladder (KUB) film may clarify the diagnosis. No indications for antenatal intervention exist for solid lesions.

Neuroblastoma is the most common solid malignant tumor in neonates and is characterized by its variability in presentation.[340,341] This tumor affects 1 in 7000 children, with 40% of cases diagnosed in children less than 1 year of age.[342] The exact origins of neuroblastoma have not been elucidated, but genetic abnormalities of chromosomes 1p and 11q have been reported.[343] The tumor is often identified prenatally.[341,344–347] In addition to prenatal ultrasound, fetal MRI can contribute to the prenatal evaluation.[336,348] If not detected by prenatal imaging, many children still present with a palpable abdominal mass. *Neuroblastoma has classically been described as a firm, fixed lesion that may cross the midline. Children may also present with bulky metastatic disease that includes a palpable liver and subcutaneous nodules that characterize stage IV-S disease.* This form usually undergoes spontaneous regression.[349] Imaging by ultrasound can usually suggest the diagnosis. Confirmation is made by CT scan or MRI. Nearly half of neuroblastomas arise in the adrenal glands, with extra-adrenal retroperitoneal locations making up another 25%.[350] These studies show a lesion that displaces the kidney but does not arise from the kidney (Figure 6.10). The appearance of a tumor arising from the kidney will cause a beaking effect of the renal tissue (Figure 6.11). Despite modern imaging techniques, the diagnosis of neuroblastoma may be confused with other less common conditions, such as pulmonary sequestration.[351] Cystic neuroblastomas detected prenatally have also been reported, so the diagnosis should not be excluded on the basis of a cystic component.[352–357] Most neuroblastomas cause elevations of urinary catecholamines, which should be checked in all such patients.

The International Neuroblastoma Risk Group designed a new staging system (INRGSS), with specific image-defined risk factors (IDRFs) based on preoperative CT or MRI.[358] Histologic confirmation through tissue biopsy and serum or urine catecholamines or metabolites are also important to the staging system.[359] Many factors, including age at detection and location, affect overall outcome. In the United States, the Children's Oncology Group (COG) risk assignment, based on the International Neuroblastoma Staging System (INSS) stage, *MYCN* amplification, tumor cell ploidy (DNA index), and

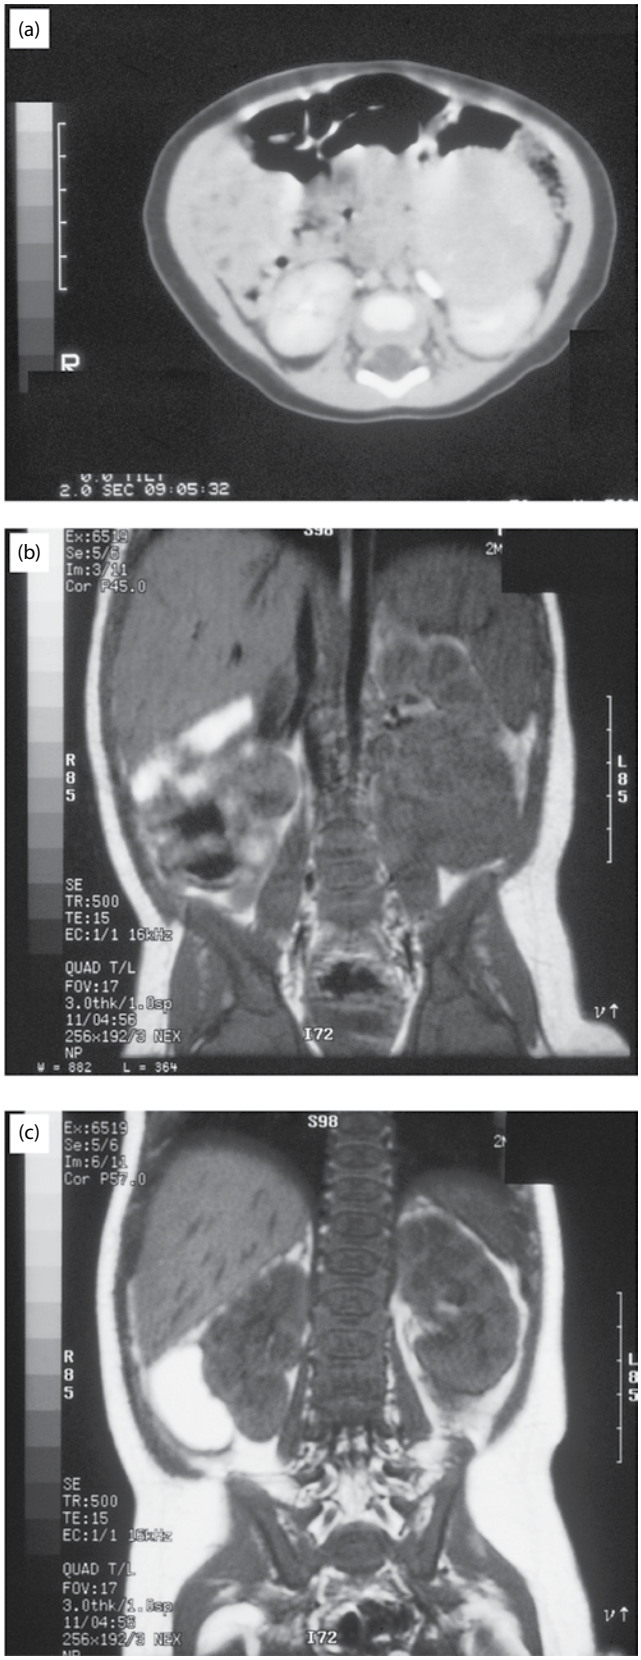

FIGURE 6.10 (a) CT scan showing displacement of the kidney by neuroblastoma (note that there is no beaking of the renal tissue). (b) MRI showing neuroblastoma in relation to the kidney. (c) MRI showing normal renal contour confirming that the tumor is separate from the kidney.

histopathology (Shimada classification), is widely used to classify neuroblastoma as low, intermediate, or high risk.

Early diagnosis and treatment may be critical in some cases.[360] However, information derived from countries with mandatory postnatal screening for neuroblastoma suggests that many tumors detected in the perinatal period regress. Therefore, some infants diagnosed very early may have unnecessary interventions that do not improve mortality.[342,361–364] The COG is currently conducting an observation pilot study for children presenting with perinatal neuroblastoma. Specific inclusion criteria are age of <3 months and sonographically identified adrenal mass that is <16 mL in volume, if solid, or <65 mL if at least 25% cystic, and which does not cross the midline.

Currently, children less than 1 year of age with prenatal or perinatal detection of a neuroblastoma may potentially be observed, with surgery reserved until the patient has symptoms or the mass increases in size.[350,365] Stage 4S patients, who are by definition less than 1 year of age and have limited metastases, may also be observed initially if histology shows a lack of high-risk features. Treatment varies from observation to surgery for those patients with early-stage localized disease, but there will likely be a trend toward increasing observation.[365] Multimodal therapy, including chemotherapy and radiotherapy, is indicated in patients

with intermediate- and high-risk disease. Several clinical trials of experimental drugs continue, as prognosis for high-risk patients is still poor, even for infants.[350,366] Treatment protocols are available through the COG.[360,367–369]

Sacrococcygeal teratoma presents with an estimated incidence of 1 in 21,000 births.[370] Most are benign, but malignant transformation can take place and the incidence of malignancy increases with delayed resection.[371] The majority occurs in females, but malignancy is slightly more common in males.[372] Intrapelvic lesions may be difficult to diagnose. The presumptive in utero diagnosis has been made by ultrasound. When this lesion is suspected in the postnatal period, it is best evaluated CT or MRI.[350,373] The tumor may cause obstruction of the urinary tract with resultant hydronephrosis. Treatment typically consists of surgical excision. Serum α-fetoprotein can be elevated in malignant tumors and can aid in the detection of recurrence.[374] Long-term urologic sequelae are possible, including neuropathic bladder, and are more likely with higher lesions.[374] A detailed urologic workup, including urodynamic studies, should be performed if any suspicion for neurogenic bladder exists.

Congenital mesoblastic nephroma is a rare renal tumor that is the most common solid renal mass in children less than 6 months of age (50%). Eighty percent of these lesions are discovered in the first month of life.[375] Congenital mesoblastic nephroma may frequently be detected prenatally, where it is associated with polyhydramnios in approximately 70% of cases,[376] or may also be detected by routine child screening ultrasound in countries where this is performed.[377] Typically, the lesion is noted as a solid intrarenal mass on sonogram that appears fibroid when removed (Figure 6.12).[378] A cystic form can also occur (Figure 6.13).[375] Pathologically, the tumor can be divided into two groups: classic and cellular. The classic lesion represents one-third of cases and is microscopically similar to a leiomyoma and does not metastasize.[379,380] The cellular variant has the potential for local recurrence and metastasis and may be diagnosed slightly later in life.[377,380,381] In utero treatment usually consists of observation and management of polyhydramnios, with its attendant complications. Postnatally, nephrectomy is recommended. In cases where metastases have occurred, chemotherapy may be warranted.[381,382] Fortunately more than

80% of tumors are low stage.[383] Hypercalcemia requiring treatment has been documented but usually resolves after nephrectomy.[381] Cases requiring urgent surgery following tumor rupture and hemorrhage have been reported.[384,385] Disease-free and overall survival are excellent, at near 95% following resection.[377,386]

Although Wilms' tumor is the most common renal tumor in children, it occurs infrequently in the neonatal period.[387,388] In children less than 6 months of age, congenital mesoblastic nephroma is a more common cause of a solid renal lesion; however, Wilms' tumors, rhabdoid tumors, clear cell tumors, renal cell carcinoma, angiomyolipoma, and ossyyfing tumors are known to occur.[383,388–390] Most of these present as a neonatal abdominal mass, and less frequently as hematuria, paraneoplastic syndromes, or hypertension.[381,391] Wilms' tumor has also been detected by prenatal ultrasound evaluation.[392–395] Associated findings in the prenatal period include fetal hydrops and polyhydramnios.[381] Postnatally, these children may have a palpable mass and, in some cases, hypertension. Children born with known associated syndromes, such as aniridia, Wilms tumor, anaridia, genitourinary anomalies, mental disability (WAGR), Denys–Drash, or Beckwith–Wiedeman, develop tumors at a younger age and are more likely to have bilateral lesions; therefore, surveillence ultrasound should be performed.[387,396] Bilateral nephroblastomatosis, aniridia, and 11p13 deletion result in the development of Wilms' tumor in close to 100% of affected individuals (Figure 6.14). These patients may develop bilateral Wilms' tumor, requiring nephron-sparing surgical techniques. Evaluation of the vascular anatomy is best performed with magnetic resonance angiography (Figure 6.15).[397]

The treatment is based on stage and the histology and genetics of the tumor. Approximately 90% of tumors have favorable histology, with the remaining 10% comprising unfavorable variants, including clear cell, anaplastic, and rhabdoid types.[350] Treatment involves surgery, chemotherapy, and sometimes radiation therapy. Debate continues over the merits of primary surgical excision with adjuvant chemotherapy and radiation based on findings, as recommended the National Wilms Tumor Study Group (NWTS), versus neoadjuvant chemotherapy prior to surgery to facilitate surgery and decrease tumor spillage, as recommended by the International Society of Pediatric Oncology (SIOP). Neoadjuvant chemotherapy is recommended by both groups for tumors that appear unresectable, have significant vascular involvement, or are bilateral.[350] The common standard chemotherapy agents utilized include vincristine, doxorubicin, and dactinomycin. Both protocols have good success rates, with overall survival rates of greater than 90%,[398] and there is a great deal of effort to maintain these results while reducing morbidity. The NWTS is currently continuing to evaluate the safety of avoiding chemotherapy in those with a very low risk of recurrence after initial results showed increased risk of recurrence but no impact on overall survival.[399] Efforts to minimize morbidity or treatment must be balanced against the success of aggressive initial

treatment. Salvage therapy after recurrence is much less successful, with rates of 50% for those with favorable histology and even lower rates with unfavorable variants.[350]

Renal vein thrombosis (RVT) may be the cause of a mass in a neonate. *The characteristic clinical presentation of RVT, an enlarged kidney, hematuria, and proteinuria in an ill infant, is only present in a small percentage of patients* (Figure 6.16), but prevalence of each sign individually is near 50%.[400] Male-to-female and left side–to–right side ratios are both approximately 2:1. Seventy percent are unilateral.[400] Low platelet counts due to consumption by the developing thrombus may be seen. Infants appear to be predisposed to this condition because of lower renal arterial and venous flow rates than older children and adults. Reports of prenatal diagnoses of RVT are now commonplace.[400–402] RVT is most commonly associated with risk factors that include dehydration, sepsis, birth asphyxia, maternal diabetes, polycythemia, cardiac disease, protein C deficiency, twin–twin transfusion, and the presence of an umbilical catheter.[402,403] In addition, the significance of prothrombotic risk factors, such as factor V, are increasingly being recognized.[404,405] The thrombosis starts in the venules within the kidney and progressively extends to the major renal vein or veins. The diagnosis is most commonly made by ultrasound (Figure 7.29).[406,407] Initially, the lesion appears as highly echogenic streaks within the kidney. Subsequently, the kidney becomes enlarged and echogenic, with loss of corticomedullary differentiation.[408]

Treatment of RVT is initially supportive, with hydration and correction of any predisposing abnormalities.[407,409] Recent guidelines from the American College of Chest Physicians (ACCP) recommend unfractionated or low-molecular-weight heparin therapies for the treatment of unilateral RVT with extension into the inferior vena cava.[410] Initial thrombolysis with tissue plasminogen activator and anticoagulation therapy with unfractionated heparin, followed by continued anticoagulation with unfractionated or low-molecular-weight heparin, is recommended for those with bilateral thrombus.[410–412] Certain studies have suggested that those who receive aggressive therapy with anticoagulants fare better than those who do not,[402] but either supportive care alone or heparin is acceptable for unilateral RVT.[410] Optimal treatment for unilateral RVT in the setting of renal impairment or prothrombotic factors is not defined.[407]

Patients with unilateral thrombosis usually do well, while those with bilateral thrombosis have a higher rate of complications, such as renal failure.[400,413] Approximately 20% of patients will have persistent hypertension, and all patients must have long-term monitoring of renal function and evaluation for hypertension.[400,414,415]

Renal artery thrombosis does not commonly present as a neonatal mass but may be a cause of renal failure if bilateral.[416,417] The occurrence of this disorder has increased significantly in relation to the increased use of umbilical artery catheters, despite the fact that a causal relationship was identified some time ago.[418] Recent research has suggested that both short- and long-term umbilical artery catheterization may produce pathologic changes in the arterial wall.[419] The diagnosis is commonly made with Doppler ultrasound, which demonstrates the absence of flow in the renal artery, but CT has made the diagnosis when ultrasound was normal.[420] Treatment options include supportive measures, antithrombolytics, and surgery, depending on the extent of thrombosis and whether aortic involvement exists.[421–423]

Neonatal adrenal hemorrhage is associated with traumatic or difficult labor, neonatal hypoxia, septicemia, RVT, or coagulopathy.[424] Traditionally, it is believed that the relatively large size and vascularity of the newborn gland predisposes it to bleeding. Presenting signs include neonatal jaundice, paleness and/or flank mass, discoloration of the scrotum, and hypotonia or lethargy or hypotension.[425] Screening ultrasound examination gives an

estimate incidence of 1.9 per 1000 births.[426] There is a right-sided predominance, and 10%–15% present bilaterally.[425,426] Diagnosis is usually made by ultrasound,[424] and antenatal diagnosis has been made in the second and third trimesters (Figure 6.17). Identification by ultrasound is usually reliable, but in some cases, it is difficult to differentiate from an adrenal neuroblastoma (Figure 6.18).[427–429] In difficult cases, CT and MRI may be helpful in the diagnosis.[430,431] Negative urine catecholamines also support the diagnosis of adrenal hemorrhage.

Experience has confirmed the initial belief that the majority of infants with adrenal hemorrhage require no treatment except for occasional phototherapy and, rarely, transfusion.[425,432,433] Resultant adrenal insufficiency has been reported in cases of bilateral hemorrhage[434] but overall is uncommon.[424] Observation for resolution and monitoring of hematocrit and bilirubin should be routine. Rarely, steroid replacement for temporary adrenal insufficiency is required.

Rhabdomyosarcoma is an uncommon neoplasm of the lower urinary tract in children. Lesions may occur in the bladder, prostate, vagina, or uterus (Figure 6.19). Presentation in infancy depends on the organ of origin and may include hematuria, vaginal bleeding, or obstruction of the urinary tract. Treatment is multimodal, with chemotherapy typically used as the primary treatment and radiation therapy and surgery used for local control.[435–437] As a result of collaborative efforts by the Intergroup Rhabdomyosarcoma Study, treatment results for these patients have improved dramatically in the last 40 years. Current efforts are focused on improving results in high-risk patients by use of additional chemotherapy agents and reducing treatment-related morbidity and mortality in all groups.[437–440] Debate continues over the merits of radical versus more conservative surgery,[440–442] but there is a trend toward less radical surgery in recent years.[437]

Gonadal tumors are rare in children, and their presentation as a lower abdominal mass is extremely uncommon. They may occur as an ovarian mass or as a mass in an undescended testis.[443–445] Mature teratomas are by far the most common tumor in both ovaries and intra-abdominal testes, followed by immature teratomas, and germ cell

tumors.[446–448] Treatment for these tumors is dependent on stage and histology. Multimodal therapy may well include surgery, chemotherapy, and radiation, which may be indicated for aggressive tumors.

SCROTAL MASSES

Identification of a scrotal mass commonly results in an urgent consultation. In the nonverbal infant less than 1 year old, pain will likely present with inconsolability, but otherwise, history plays very little role.[449]

The specific differential diagnosis of neonatal scrotal masses includes

- Hydrocele
- Lesion secondary to patent processus vaginalis (hernia or hydrocele and meconium)
- Perinatal torsion
- Paratesticular abscess
- Testis tumor

The physical examination should focus on identifying the location of the mass in relation to the testis and the orientation of the testis. Careful palpation will identify torsion of appendices, such as the appendix testis, both anterior and superior appendices of the epididymis, and the hydatid of Morgagni, which is located in the posterior inferior epididymal testicular ridge.[450] If the mass is large enough as to obscure palpation of the testis, then transillumination is helpful since it rapidly discriminates solid from fluid-filled masses. Occasionally, a plain abdominal film may be helpful in identifying bowel gas in the scrotal mass that would indicate an inguinal hernia with bowel in the scrotum, or calcification suggesting old meconium. If the mass is associated with thickened cord structures, or if it can be reduced, a hernia is also likely.

Ultrasound examination can differentiate solid and cystic masses, as well as the mass's relationship to the testis and epididymis, but is generally unnecessary since most masses represent hydroceles. Doppler ultrasound can often confirm blood flow, but can be misleading in the small child.

Hydroceles are the most common scrotal masses and can be associated with a patent processus vaginalis (communicating hydroceles or hernias). They may be unilateral or bilateral, and sometimes alarmingly large. Other lesions that result from a patent processus vaginalis include meconium mass, hemoscrotum from intra-abdominal hemorrhage, and tumor seeding from renal or adrenal tumors.[451–455] Spontaneous rupture of the bowel can occur during fetal development, resulting in meconium peritonitis. If the processus vaginalis is still open at that time, the meconium can fall into the scrotum and present as a solid mass at birth. Stippled calcification is usually present. Likewise, other anomalies, such as adrenal hematomas, neuroblastoma, and Wilms' tumor, can also seed the scrotum through a patent canal and should be considered in the differential diagnosis of neonatal scrotal masses. All these suggest the utility of abdominal ultrasonography upon discovery of the scrotal mass.

Perinatally, firm bilaterally enlarged scrotal masses may be hydroceles, but the diagnosis of *bilateral perinatal testis torsion* should be considered.[456,457] Perinatal torsion is comprised of both prenatal and neonatal torsion. Prenatal testis torsion is also referred to as extravaginal torsion, intrauterine torsion, and antenatal torsion and occurs before birth. There is controversy over the mechanism of the torsion, risk of bilaterality, and need for and timing of contralateral fixation.[458–461] When torsion occurs before delivery, it has been thought to occur extravaginally, involving the entire spermatic cord and its tunics. Some physicians believe that this process can occur very early in the pregnancy, and that it is responsible for most instances of testicular agenesis.[462–464] It is impossible to determine whether all cases are extravaginal, and at least some probably represent intravaginal torsion, as seen in older boys. When torsion occurs prior to delivery, the presentation is one of a nontender, discolored, solid scrotal mass. Doppler ultrasound is generally accurate in confirming the diagnosis.[465–469] The torsion is most often unilateral, but more than 45 bilateral cases have been reported.[459,467,470–485] In cases of suspected bilateral torsion or an initial presentation of unilateral torsion followed by any acute scrotal changes, emergent surgical exploration is clearly indicated.

Unilateral prenatal torsion with an apparently normal contralateral testis is more controversial. Some favor delayed contralateral fixation after 1–3 months.[475,486] The reasons for this approach include risks of neonatal anesthesia, a low likelihood of bilateral torsion, and the ability to diagnose contralateral torsion by clinical exam. Parents are instructed to monitor the child closely at every diaper change for any acute scrotal changes. If this approach is taken, it is important to document contralateral blood flow by Doppler. Others favor early surgical exploration on an emergent or urgent basis in any case of perinatal torsion, including unilateral prenatal torsion.[486,487] A strong case has been made for early exploration, with orchiectomy when the testis is necrotic, and contralateral fixation, as many examples of subsequent contralateral torsion have now been reported.[488–490] Other arguments for early exploration include the relative safety of anesthesia in the neonatal period; the possibility of testicular salvage (10%), particularly the hormonal function; and the confirmation of diagnosis. Additionally, recent studies suggest that 36%–50% of contralateral testes found to be ischemic at the time of surgery showed blood flow on preoperative Doppler studies.[471,487] There will likely be no clear consensus anytime soon. Indeed, a recent survey of pediatric urologists found that 10% preferred immediate exploration, 57% preferred delayed exploration, and 33% preferred observation alone.[461] The best approach in any particular scenario needs to take into account many factors, including access to specialized pediatric anesthesia teams and NICU support.

Testis tumors are also seen in the neonatal period extremely rarely. Historically, yolk sac tumors were reported to be the most common testicular tumor in the newborn period.[491] These data may have been biased however, and recently data have suggested that most prepubertal testicular tumors are benign, with teratoma being the most common (Table 6.5).[492–496] Data specific to the newborn period are not available from these studies. Extrapolating from the average age of the patients, some

TABLE 6.5 Prepubertal testicular tumors (% incidence by publication)

	Levy et al.[491]	Metcalfe et al.[492]	Pohl et al.[494]	Shukla et al.[493]	Bujons et al.[495]	Wang et al.[496]

Hamartoma	5				7	
Epidermal cyst		10	14	13	27	6

studies would suggest yolk sac tumors to be more prevalent in younger patients,[492] while others do not suggest this difference.[496] Regardless, the proportion of benign tumors appears higher than previously thought, and testis-sparing surgery is increasingly being utilized.[492–498] Fortunately, a tumor's malignant potential can typically be identified by preoperative imaging and serum α-fetoprotein.[492,493,495,496,498,499] As long as proper precautions are taken to allow for radical orchiectomy in the rare event of an unexpected malignant tumor, long-term outcomes for testis-sparing surgery have been good.[492–496,498] Early radical surgical removal is the recommended treatment for those with malignant potential, with chemotherapy in selected cases.

Paratesticular abscesses mimicking torsion have been reported but are very rare. Causative organisms include *Staphylococcus*, *Salmonella*, and *Klebsiella*. Methods of scrotal contamination include hematogenous, urinary, and peritoneal via patent processus vaginalis, or direct contact.[500–502] Drainage of the abscess is typically accomplished by scrotal exploration. Initial broad-spectrum antibiotics should be tailored to culture when available.

BLADDER EXSTROPHY–EPISPADIAS COMPLEX

The prenatal identification of the bladder exstrophy–epispadias complex is uncommon due to the rarity of the disease and an estimated 10%–25% detection rate by prenatal screening sonography (Figure 7.6).[503–505] However, the pediatric urologist may be called on to consult prenatally regarding postnatal treatment and outcomes.

The five most commonly identified sonographic findings are (1) no visualization of the bladder, (2) a lower abdominal bulge, (3) a small penis and anteriorly placed scrotum, (4) a low-set umbilicus, and (5) abnormal widening of the iliac crests.[505] Omphaloceles are usually associated with a midline defect at the umbilical insertion; gastroschisis most frequently consists of a small, right-sided paraumbilical defect; and large lateral defects usually occur in the limb–body wall complex. In addition, specific organ evisceration and other associated abnormalities assist in the differential diagnosis.[506,507] Prenatal ultrasound at 20 weeks' gestational age may be unable to determine gender in up 80% of cases.[503] Fetal MRI is being increasingly used in the prenatal diagnosis and to provide more accurate detail in cases of exstophy.[503,508,509]

The challenge in the prenatal identification of these abnormalities, as with any prenatal diagnosis, is to provide counseling that is both timely and accurate based on the information available regarding a particular case and the condition as a whole.[510,511]

At birth, an exstrophic bladder, an abdominal wall defect, epispadias, pelvic diastasis, VUR after bladder closure, and bilateral inguinal hernias characterize the anomaly. The infant is otherwise healthy. The best approach is to involve a physician familiar with the immediate and long-term outcome of patients with these complex reconstructive problems, who should coordinate the initial management and transfer, if the baby is born at an outside institution. The initial treatment is to protect the exposed bladder mucosa. If a plastic umbilical clamp was placed in the delivery suite, it should be removed and replaced with a suture. If possible, nothing should come into contact with the bladder mucosa. A modified humidifier tent can be placed over the bladder, but for transport, a cellophane nonadherent dressing may be utilized, while gauze or petroleum products should be avoided.[512] Transfer to a center with exstrophy experience should be considered soon after birth but is not emergent, and the child should be stabilized and adequately hydrated before travel.[512] The protection afforded by cellophane dressings is adequate enough that it has been utilized to allow patients to be discharged home prior to surgery to allow growth and parental bonding.[513] An increased risk of latex allergy has been reported in patients with urologic abnormalities, such as exstrophy, and appears to increase as the number of surgeries increases. Exstrophy patients should be cared for in latex-free environments to minimize this risk, which can have serious consequences, such as intraoperative anaphylactic reactions.[512,514,515]

Controversy continues regarding complete primary repair versus modern staged reconstruction,[516] although complete primary repair is becoming increasingly utilized.[517–519] Enthusiasm for the possibility of fewer surgeries and promotion of early bladder cycling led to increasing adoption of complete primary repair of exstrophy (CPRE) developed by Dr. Michael Mitchell.[517–520] Continued diffusion of this technique has been somewhat tempered by increasing reports of ischemic penile injuries and the fact that subsequent procedures may still be required.[521,522] The more traditional staged repair[523,524] is the most studied, with the longest reported outcomes. The first stage

involves bladder and abdominal wall closure with pelvic osteotomy in most cases (Figures 6.23 and 6.24).[523,524] Other reconstructive strategies have also been used, including the Kelly repair,[525] the Warsaw approach,[526] and the Mainz II pouch,[527] and bioengineered tissues may play a role in the future.[528,529] Exstrophy reconstruction and new imaging modalities have led to a greater understanding of sphincter and pelvic floor anatomy and function.[530,531] Patients have improved pelvic floor reconstruction and better continence rates after osteotomy.[532–535] This is likely due to better approximation of the pelvic floor muscle. In addition, there is a close relationship between bladder size and continence. In situations where capacity is inadequate, bladder augmentation, bladder neck closure, and a catheterizable stoma may provide the best alternative.[536–538] Debate over which reconstructive technique provides the best long-term outcome will continue, but has little impact on the immediate neonatal care, which focuses on bladder protection, parental counseling, and timely referral to a center with exstophy experience.

Regardless of the technique employed, a complete understanding of the underlying anatomical abnormalities and the surgical approach is a requirement for the appropriate counseling of prospective parents to help them understand what will be involved in the early life of these patients. Long-term data, including the psychosocial and physical outcomes of patients treated with various surgical approaches, continue to accumulate, but patient numbers are still small. Quality of life tends to be near normal in regard to education, family life, employment, and social interactions.[539–542] The males were concerned about the appearance of their external genitalia,[543] even though their sexual function was preserved.[544] The female patients were less concerned about disfigurement and had normal sexual function and sexuality.[545] Fertility can often be achieved for men and women with exstrophy but may require assisted reproductive techniques.[545–547]

PRUNE BELLY SYNDROME

Deficient abdominal wall musculature, cryptorchism, and urinary tract dilation characterize this syndrome. Other names include triad syndrome, Eagle–Barrett syndrome, and abdominal muscular deficiency syndrome. The presumptive prenatal diagnosis has been made as early as 11–14 weeks' gestation and is becoming more common with improved imaging techniques.[548–550] Keys to the antenatal diagnosis include distended thin-walled bladder, stenosis or dilation of the entire urethra, and hydronephrosis and hydroureter with or without oligohydramnios.[549,551] Posterior urethral valve (PUV) can sometimes be distinguished from prune belly syndrome (PBS) by a thickened bladder wall or a keyhole sign, but the distinction can be difficult, especially when oligohydramnios occurs.[99,552] One terminated fetus had urethral atresia with histologically normal kidneys.[553]

The overall incidence is approximately 3.8 per 100,000 live male births, with black children affected at a disproportionately high rate.[554] The spectrum of this disease is wide. Although predominantly affecting males, a female variety has been described.[555–557] It ranges from in utero demise to renal dysplasia and subsequent renal failure to normal renal function. The in-hospital mortality rate is nearly 30% for those born with PBS and has not significantly improved in recent decades.[554] The pathogenesis is not completely understood,[558] but a high concordance rate in twins, apparent familial patterns, and varying incidence between ethnic groups point to a genetic component.[554,559–562] Limited data have implicated the *HNF1B* gene on chromosome 17q12,[563,564] but clear evidence of its effect is still lacking.[565]

Antenatal intervention with vesicoamniotic shunting[566] or serial vesicocentesis and amnioinfusions[567] have been described and may gain increasing use with improved prenatal diagnosis and advancement of fetal intervention. The postnatal evaluation should include physical exam, urinalysis and urine culture, serum creatinine and electrolytes, sonography, VCUG, and renal scan when indicated, although VCUG can be avoided to reduce the risk of early UTI.[568–570]

Initially, medical treatment (i.e., antibacterial prophylaxis and perhaps circumcision in babies with reflux) and close surveillance are indicated in all but the most severe cases, where vesicostomy or upper tract diversion may be needed.[550,570–574]

In the long term, a combination of continuous antibacterial prophylaxis, well-planned surgery, and close surveillance is the best means to ensure an optimal outcome.[550,570,572,574–578] The severity of the congenital renal dysplasia, a nadir creatinine greater than 0.7 mg/dL, recurrent pyelonephritis, and renal obstruction all correlate with eventual development of renal failure.[496,576]

Treatment of the undescended testes should be similar to that recommended for other patients with abdominal testes.[550] Early orchidopexy should be accomplished and may be facilitated by laparoscopy.[579,580] Patients requiring Fowler–Stephens orchidopexy will typically still have adequate testicular health for spontaneous puberty and sexual function.[581]

No prune belly patient has been known to father a child without assisted reproductive technologies. However, early testis biopsy has identified spermatogonia,[582,583] and there has been one report of successful pregnancy following intracytoplasmic sperm injection.[584] The histologic findings of significantly reduced spermatogonia and marked Leydig cell hyperplasia suggest that the pathology of the testis in prune belly syndrome is secondary to more than just its abdominal location. Testis tumors have developed in these patients.[585–587]

ANORECTAL MALFORMATIONS

Anorectal malformations (imperforate anus) are congenital lesions of the cloaca that are often associated with urological abnormalities (Figure 6.20). There is also a high incidence of other congenital abnormalities associated with such malformations as part of the *VACTERL (vertebral anorectal cardiac tracheoesophageal renal and limb) syndrome*. There are multiple classification systems, but from a urologic perspective, the simple distinction of "high," "intermediate," or "low" anorectal lesions is probably sufficient. Low lesions are those that occur inferior to the levator muscles, high lesions occur above the levator muscles,

FIGURE 6.20 Patient with imperforate anus. (From Dr. Donald W. Hight, Connecticut Children's Medical Center, Hartford. With permission.)

FIGURE 6.21 Radiographic picture of high bowel–urethral fistula. (From Dr. Donald W. Hight, Connecticut Children's Medical Center, Hartford. With permission.)

and intermediate ones in between (Figure 6.21).[588] From a clinical point of view, most intermediate lesions are treated as high lesions. The surgical correction of these malformations is most often by a technique popularized by de Vries and Pena[589] using the posterior sagittal approach.[590,591] Laparoscopic repair has been developed in hopes that a minimally invasive technique would improve functional outcomes by minimizing trauma and scarring to the sphincteric muscles.[591,592] To date, significant clinical evidence demonstrating this benefit has yet to be shown.[593]

Associated urologic abnormalities occur in up to 20% of patients with low lesions and up to 60% of those with high lesions, although rates appear to be higher with demonstrated chromosomal abnormalities, particularly terminal delation of 13q.[594–596] The most common findings are VUR, neuropathic bladder, renal agenesis, renal dysplasia, and cryptorchidism. Female patients may have associated hydrocolpos and obstructive uropathy requiring urgent urologic intervention.

It is not surprising that there is a high incidence of neuropathic bladder given the association of vertebral abnormalities, most commonly a tethered cord, especially with high lesions. The overall incidence of neuropathic bladder may be as high as 50%, and is more common with high and complex lesions.[594,597,598] The significant morbidity and mortality from associated renal insufficiency underscore the importance of the urologist's role in patients with anorectal malformations.

All patients should be evaluated with a renal bladder sonogram and VCUG at birth, regardless of the height of the defect. Spinal ultrasound or MRI is often needed, as occult defects, such as tethered cord, can be missed on plain films.[599,600] Evidence of neuropathic bladder has been demonstrated even in patients with low lesions and normal spinal imaging.[598,601] Urodynamics should be performed on children with high lesions, spinal abnormalities, or other suspicion of abnormal voiding, such as dilated upper tracts on ultrasound.[598] Specific treatment will then be based on urodynamic findings, as in other cases of neuropathic voiding dysfunction.

CIRCUMCISION INJURIES

Despite continued controversy over the risks, benefits, and ethics of circumcision, it remains the most common surgical procedure in newborns, with approximately 1.2 million operations performed annually in the United States. After a rise in circumcision rates in the United States during the 1990s, from ~48% to ~61%, rates declined to ~55% by 2004 and have held essentially stable since. There are significant regional differences, with only 24.6% of newborn males being circumcised in the western states.[602] Absolute indications for neonatal circumcisions are few.[603,604] Circumcision in infants with known bleeding disorders, hypospadias, and congenital anomalies of the penis; buried penis; or prematurity should be delayed to a later date.[605] In neonates with prenatally detected hydronephrosis, especially when reflux is identified, circumcision may be recommended because it decreases the likelihood of an early UTI.[109,606,607] Reports demonstrating a marked change in the periurethral and glanular

bacterial flora in boys after circumcision support this practice.[608] Indications for circumcision in older children include persistent phimosis, paraphimosis, and recurrent balanitis. A viable alternative to circumcision in infants and older children is the use of steroid cream.[609–611] This is typically accomplished by applying betamethasone cream (0.05%–0.2%, with or without the addition of hyaluonidase) to the prepuce twice daily for 4–8 weeks. Success rates of roughly 70%–90% have been reported. Topical therapy may be less effective when there is balanophostitis or a lack of meatal exposure.[612] Paraphimosis is typically treated first with pressure on the edemetous preputial skin and reduction of the paraphimotic skin. Subcutaneous injection of hyaluronidase (150 U/cc) after topical anesthetic, such as EMLA cream (2.5% prilocaine and 2.5% lidocaine; Astra Pharmaceuticals, Westboro, Massachusetts), has also been used with excellent results. The hyaluronidase reduces the edema almost immediately, facilitating an easier and less painful reduction of the foreskin.[613] Complications related to hyaluronidase injection are very rare, but isolated cases of anaphylaxis, shock, and hypovolemia have been reported when the medication is given intravascularly. If the glans cannot be replaced, a dorsal slit incision in the phimotic skin allows reduction.

Complications of circumcisions are infrequent, occurring in 0.2%–3% of cases.[614]

1. Acute complications
   a. Bleeding
   b. Infection
   c. Laceration
   d. Amputation, usually partial
   e. Urinary retention
   f. Skin loss
   g. Necrosis, sometimes due to overuse of cautery
   h. Necrotizing fasciitis
2. Nonacute complications
   a. Skin excess
   b. Skin asymmetry
   c. Skin bridges
   d. Skin chordee
   e. Epidermal inclusion cysts
   f. Concealed (buried) penis
   g. Phimosis
   h. Meatal stenosis
   i. Urethrocutaneous fistula
   j. Circumcision despite hypospadias, removing skin needed for repair
   k. Plastibell specific
   l. Lymphedema

The majority of circumcision complications are minor.[615–622] The incidence of complications is probably higher than reported in the urologic literature since many are treated without referral and some do not present until the patient is much older. *Complications are best prevented by strict attention to the details of the procedure, which include sterile technique, hemostasis, protection of the glans, and removing the appropriate amount of inner and outer preputial skin.*[623–625]

Certain anatomic variations may predispose to complications during neonatal circumcision. Mayer et al. suggested that a prominent fat pad, penoscrotal webbing, or prematurity is associated with a higher incidence of circumcision complications.[626] When complications occur, immediate attention and treatment is the best management.[627–631]

Bleeding is best managed by pressure, placing an absorbable stitch, or with electrocautery, although electrocautery should never be used with a metallic clamp device in place because of the risk of penile necrosis. Most of the cases that require immediate repair involve laceration or amputation of a portion of the glans (Figure 6.22). Commonly, these result from a circumcision done using a Mogen clamp placed at an angle incorporating the frenulum, which draws up the glans into the clamp.[629] If the amputated portion of the glans can be retrieved, it can be reapproximated with absorbable sutures. When amputation occurs, the amputated portion of the glans should be wrapped sterilely and kept cool on ice, but not submerged in saline. In most instances, it can be reattached utilizing long-lasting absorbable sutures.[628,629,631,632] Amputation of a portion of the penis involving the urethra should also be repaired by immediate reconstruction.[633] Results are best if reapproximation occurs within hours of the injury; however, successful reapproximation after delays of up to 18 hours have been reported.[634] Most urethral injuries should have a staged reconstruction, although fistulae can be closed immediately if recognized[630] (Figures 6.23 through 6.33).

Penile skin loss as a result of circumcision can usually be managed conservatively by application of antibiotic impregnated gauze. Ingrowth of skin usually results in a good cosmetic appearance. Skin grafting is rarely necessary.

Sometimes an apparently normal penis with a complete circumferential prepuce is found to have a hypospadiac meatus when the skin is incised or retracted. This rare form of hypospadias is called megameatus with intact prepuce. The circumcision should be discontinued and any remaining skin left attached for possible later use in hypospadias repair. Plastibell circumcisions have their own specific complications, including a higher incidence of delayed wound infections and retained plastic cuff. Concealed or buried penis can result when the glans penis recedes below the circumcision scar and the scar then contracts[635] due to insufficient removal of inner prepuce.

INTRAOPERATIVE CONSULTATIONS

The best approach to intraoperative consultations is to take the time to obtain a complete history. This usually is chart-based but may include talking to the parents prior to making a quick decision about a complex question. This is also the case when one is asked about a surgical finding or called to address a surgical complication. After the chart review and appropriate history, it is best to scrub into the case and review the exact location of the lesion from the skin to the region of question. One must take a fresh look at the situation and not rely totally on the primary physician. When any questions arise that deal with surgical excision of a mass, multiple radiologic modalities can be used intraoperatively, and frozen section sampling is available. *There is little to be lost in closing the patient who needs further evaluation that cannot be undertaken in the operating room, and reoperating when the problem is better understood.*

Many unusual structures may be found during a pediatric hernia repair. Among these is the finding of reproductive organs appropriate to the opposite sex. Although rare, this will usually generate an intraoperative consultation. In males, the finding of female organs, such as a fallopian tube or uterus, is termed persistent Müllerian duct syndrome or hernia uterine inguinale.[636] *The cause of this anomaly is a failure of Sertoli cell production of Müllerian inhibiting substance* (MIS), leading to feminization of pelvic structures. The testis should be undescended, but otherwise the patient is phenotypically male. Intraoperative biopsy confirms the presence of a normal testis. Testicular biopsy should be obtained from pole to pole, as opposed to the typical excisional biopsy used for infertility workup, to increase the chance of discovering an ovotestis if present.[637] Excision of the female structures should be performed with

FIGURE 6.25 Newborn with myelomeningocele.

care, avoiding injury to the adjacent functioning Wolffian duct structures. Historically, removal of the Müllerian structures was avoided by many to avoid potential injury, as there was little evidence of malignancy.[638,639] However, the routine removal of Müllerian structures, which was previously espoused by some,[640] has gained strength by an increasing number of reports of Müllerian malignancies in these patients.[641–643] Removal may be facilitated by laparoscopy.[643] In phenotypic females, the finding of male reproductive structures during hernia repair suggests androgen insensitivity syndrome. Here, the timing of excision of the male gonads is controversial: if removed early, exogenous estrogens must be administered to induce normal maturation at puberty; if left in situ until puberty, the testis must then be removed because of the high possibility of developing a gonadal tumor.[644–646] As an intraoperative consultation, it seems reasonable to remove the testis in cases of complete androgen insensitivity syndrome, especially for young infants, if a detailed discussion is conducted with the parents. However, there is little risk in leaving the testis in place and coming back later after the family has had time to make informed decisions in a less stressful environment.[646] Other investigations can be carried out during the initial intraoperative consultation after consent is obtained from the parents, including thorough physical exam, cystoscopy, vaginoscopy, and intraoperative x-ray studies.[637] Laparoscopic removal of the testis allows for a minimally invasive approach yet permits direct molecular analysis of the specimen.[647] More than 40 other tissues have been identified in and around the hernia sac. They include normal structures drawn into the sac, organ duplications as "rests," inflammatory lesions, tumors, and drainage from the abdomen into a patent processus vaginalis:[648]

   d. Blood

Unusual findings in the spermatic cord of which the urologist should be aware include those listed above, particularly ectopic adrenal tissue and accessory spleens.[649,650] In cases of ectopic adrenal tissue, the yellow color and an appearance similar to the normal gland usually aid identification. Neuroblastoma and Leydig cell tumor have also been reported to present as a mass in the spermatic cord.[651,652] In addition to the more common scrotal masses, heterotopic Wilms' tumor and neuroblastoma have been reported.[637] Both adrenal and splenic tissue have also been found in the scrotum, and splenogonadal fusion is not uncommon with an undescended left testis. Excision of these masses is usually best, with careful pathologic evaluation to confirm the diagnosis. In the rare event that exploration through a scrotal incision (i.e., for possible torsion) reveals a testicular mass, a separate inguinal incision should be made and radical orchiectomy performed at the internal ring. One should at least widely excise the scrotal incision site if the testicle remains intact or perform hemiscrotectomy if there is concern for contamination of the incision or after any percutaneous biopsy revealing a testicular neoplasm.[637,653]

Vasal abnormalities noted during surgery (i.e., the absence of the vas with normal testicle) should result in imaging workup postoperatively with ultrasound to assess for upper tract abnormalities, such as renal agenesis or ectopia, which have been associated with the absence of the vas.[654,655] Based on examination of pathologic specimens, the estimated risk of injury to the vas or epididymis during pediatric hernia repair is approximately 0.5%,[656] although most are probably not recognized until later in life during evaluation for infertility. Vasal injury that is identified during pediatric hernia repair mandates intraoperative

pediatric urologic consultation. Previous studies have documented the ease with which vasal trauma may occur secondary to intraoperative manipulation.[657] In cases of transection, immediate microsurgical repair is indicated, although this may be technically challenging in prepubertal boys.[658,659] Crush injuries may result in future obstruction. In these situations, the decision regarding treatment must be individualized. In most instances, observation is indicated. However, when a severe crush injury has occurred, as when a clamp is applied and closed with obvious injury, excision and primary reanastomosis are indicated.

Intraoperative consultations relating to the bladder are usually a result of trauma or iatrogenic injury during surgery. Intraoperative injury to the bladder is rare but may occur secondary to percutaneous laparoscopic procedures or during inguinal hernia repair. When it happens, it is best managed by primary closure, and bladder drainage in the postoperative period via a urethral catheter and/or suprapubic tube. Perivesical drainage is also appropriate in the immediate postoperative period. A cystogram to confirm the absence of extravasation should be performed prior to removal of drainage catheters. Rarely, during umbilical hernia repair, an urachal abnormality is discovered. In these cases, the urachus should be traced to the dome of the bladder and excised with primary closure of the bladder.[637] If the diagnosis is uncertain, an intraoperative cystogram may clarify the picture. Later, evaluation for other associated genitourinary abnormalities, which may be seen in approximately 35% of cases, is warranted.[660]

Most consultations related to the kidney or ureter occur in patients with renal trauma. As in other forms of renal trauma, there has been a movement toward nonoperative management of pediatric renal injuries, including those identified intraoperatively.[661] When called in for an intraoperative evaluation of a renal trauma, it is important to obtain at least a single-shot IVP (2 mL/kg IV bolus) to document the presence and function of the contralateral kidney if no preoperative imaging exists.[662] This may also aid in staging the renal trauma, especially if a three-phase IVP can be obtained. When an expanding retroperitoneal mass is explored after trauma, early renal vascular control should be the main objective to help prevent unnecessary nephrectomy. Selective angioembolization can play a role in specific cases of isolated segmental bleeding, but has limitations.[662] When appropriate steps are taken, the vast majority of kidneys can be saved after renal injuries.

Traumatic separation of the ureter and pelvis occasionally occurs in children. Unlike many injuries where drainage and observation is indicated, complete avulsion of the

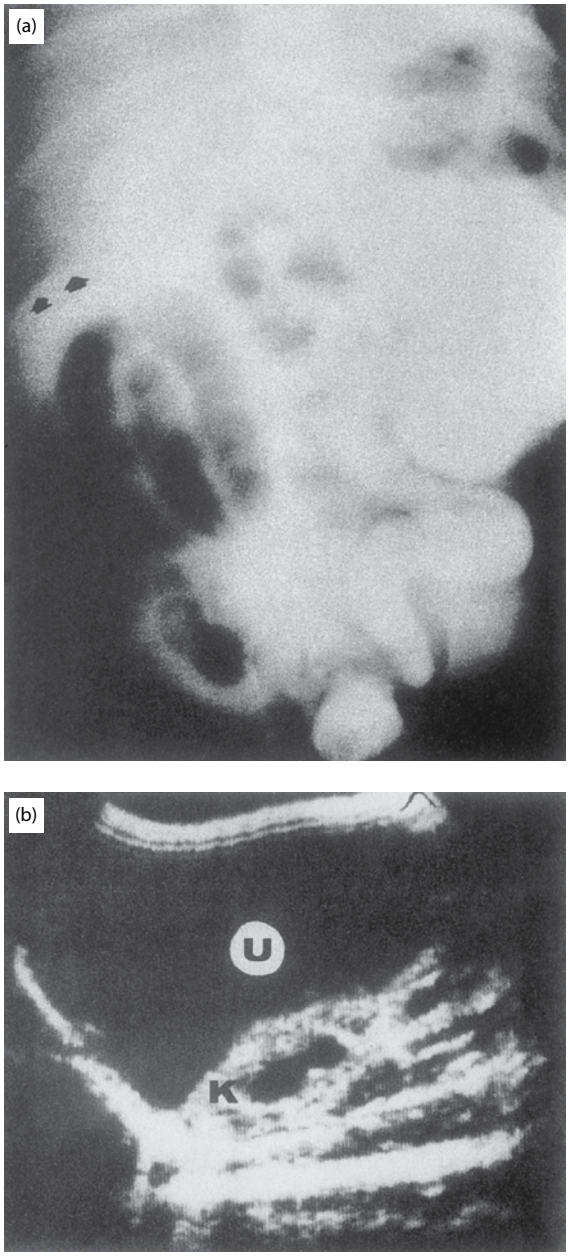

FIGURE 6.32 (a) Voiding cystourethrogram of urinary ascites. The black arrows point to the liver edge. (b) Ultrasound study showing a retroperitoneal urinoma. K, kidney; U, urine collection. (From Rittenberg M. et al. *J Urol* 1988;140:993–6. With permission.)

ureter should be surgically repaired as quickly as possible. It is a more complex procedure than a standard UPJ repair because the pelvis is almost always intrarenal and mobilization of the kidney and ureter to prevent tension on the anastomosis can be difficult. The procedure is much more difficult if the correction is delayed because of edema with subsequent scar formation. However, when called to evaluate a dilated or otherwise abnormal ureter, injured or not, temporary drainage by a percutaneous nephrostomy tube or ureterostomy may be the best course to allow accurate determination of the etiology of the abnormality before proceeding with reconstruction.[637]

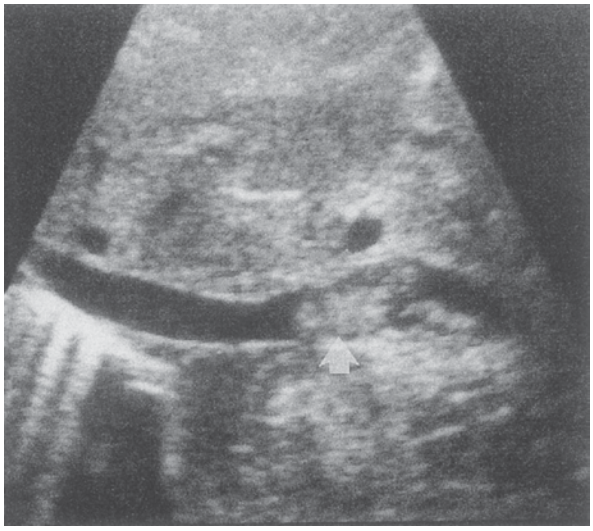

FIGURE 6.33 RVT. Ultrasound through the inferior vena cava (IVC) showing thrombus within the IVC at the level of the renal vein. (From Hibbert J et al. *Br J Radiol* 1997;70:1191–4. With permission.)

As a result of advances in imaging and thorough preoperative evaluations, consultations because of a previously undiagnosed renal mass, formerly common, are now unusual. One must consider the same differential for cystic masses as discussed earlier. Often, a dilated renal pelvis may be mistaken for a cystic mass. A solid mass is most likely a Wilms' tumor when outside of the newborn period, but other possibilities exist. Occasionally, an ectopic or a pelvic kidney may be confused with a pelvic mass and necessitate an intraoperative consultation. Reports of inadvertent nephrectomy in patients with solitary ectopic kidneys are found in the literature.[637] When it is unclear whether the mass in question is a solitary kidney, intraoperative imaging may be necessary to clarify the situation. This is critical, as reports indicate that up to 10% of all pelvic kidneys are solitary.[663] Intraoperatively, it is important to remember that ectopic kidneys may not be reniform in shape and tend to have an anomalous blood supply derived from the aorta and iliac vessels, or the superior mesenteric artery.[663] Simple needle aspiration to confirm the presence of urine may also be useful in identifying a kidney. Fusion anomalies and horseshoe kidneys may also be a source of confusion and prompt urologic consultation.

Use of laparoscopy and robotic surgery continues to increase in pediatric and adult surgery in all specialties. Intraopertive issues unique to minimally invasive techniques include port placement injuries and the decision of whether to convert to open surgery when consulted. Veress needle or port placement injury to urologic organs is rare, with bowel and blood vessel injuries being more common.[664] The bladder is the most common urologic organ inured by port or Veress needle placement,[409,665] and the more superior location of the bladder in children makes care all the more important. Actively draining the bladder by aspiration via a catheter can help to ensure it is as empty as possible. Injury to any urologic organ during surgery may go unrecognized due to the limited field of vision inherent in laparoscopic surgery. A large meta-analysis found that nearly half

of bladder injuries were missed at the time of laparoscopic surgery.[666] When an injury is recognized, the same general principles apply to a given injury as with open surgery. Nearly any repair can be accomplished laparoscopically or robotically if the surgeon is experienced, thus avoiding the need to convert to open surgery.[666,667] However, as with any intraoperative consultation, one must step back and do everything possible to ensure the best outcome. If conversion to open surgery is needed to fully gain access to or remedy the problem, it should be done.

Occasionally, the urologist will be called on to evaluate an infant for difficulty in placing a urethral catheter. Initially, properly lubricating the urethra by injecting 2% lidocaine jelly facilitates catheter insertion. Most commonly, these will be male neonates who have had multiple attempts at catheterization before urologic consultation. In these cases, a good option may be to use a curved-tip "coude" catheter, which has recently become available in pediatric sizes. When these are not available, or will not pass, a small catheter guide may be placed within a pediatric feeding tube and manipulated into the bladder. If no guides are available, bending a heavy wire suture for use as a catheter guide may be successful.[668,669] Lubricating jelly must be placed on the guide to facilitate its removal. In cases where this fails, proceeding directly to cystoscopy to evaluate the possibility of a false passage is warranted. Use of a guidewire placed under direct vision, followed by catheter placement over the wire, ensures proper catheter placement. If council tip catheters are not available in pediatric sizes, standard catheters can be modified to pass over a wire. One must be extremely careful if cutting off the tip transversely to avoid damaging the balloon. This is especially difficult on pediatric-sized catheters. Other techniques include a longitudinal cut[670] or the Blitz technique,[671] which uses an 18-gauge angiocath to guide the wire directly through the tip of a catheter. The balloon should be tested prior to insertion of any catheter that has been altered, and the alteration should be documented so there is no concern for breakage when the Foley is removed. Special precautions should be considered when needing to perform cystoscopy or other urinary tract manipulations on patients with spinal cord injuries: (1) the possibility of autonomic dysflexia for lesions at T6 or higher, (2) an increased risk of infection warranting antibiotic coverage when there is trauma or dilation of the urinary tract, and (3) the possibility that the wire may double back over itself in a small-capacity bladder, leading to placement of the Foley balloon in the urethra.[672] When the bladder is palpable, a percutaneous cystotomy may be performed under local anesthesia or in the operating room. Alternatively, a large-gauge needle placed into the distended bladder will permit insertion of a guidewire, dilation of the tract, and placement of a suprapubic catheter.

CHAPTER 7

Urinary Tract Infections in Children

Dana C. Rice, H. Gil Rushton, and Hans G. Pohl

INTRODUCTION

Advances in research have enabled us to better understand the etiology and pathophysiology of urinary tract infections (UTIs) in children, which in turn has further refined diagnostic and treatment algorithms, and the management of long-term sequelae. The role of bacterial virulence in the etiology of UTIs has assumed greater importance since it has been recognized that bacteria are genetically encoded to invade the urinary tract, evade detection by the innate immune system, and cause tissue injury. Interacting with these virulence factors are a multitude of host defense factors operating at every level of the urinary tract. Collectively, these complex host–parasite interactions determine an individual's predisposition to urinary infection.

Epidemiology

UTIs in children may be symptomatic or asymptomatic. Symptomatic infections may be confined to the bladder (cystitis), or they may involve the upper collecting system (ureteritis and pyelitis) or extend into the renal parenchyma (pyelonephritis). Age, gender, race, circumcision status, the method of detection, and presentation all influence the prevalence of symptomatic versus asymptomatic urinary infection. With 174 per 100,000 infants younger than 3 months being hospitalized each year for UTIs, it has been estimated that the annual cost to the U.S. healthcare system for hospitalization for UTI approaches $180 million.[1]

Historically, the incidence of neonatal bacteriuria has been reported as 1%–1.4%, with males predominating.[2–4] However, the actual incidence during infancy has probably been underestimated in the past, partly because of the difficulty in diagnosing UTI in this age group. In a 3-year prospective study of 3581 infants (aged 0–1 year) in Goteborg, Sweden, asymptomatic bacteriuria (ABU) was confirmed by suprapubic aspiration (SPA) of urine in 2.5% of boys and 0.9% of girls.[5] Symptomatic urinary infection occurred equally often in both sexes (1.2% of boys and 1.1% of girls). Overall, 3.7% of boys and 2% of girls had positive urine cultures during the first year of life. The male predominance noted in the Goteborg study during the first few months of life has also been reported by others.[6–9] Uncircumcised infant boys are 8–10 times more likely to have symptomatic urinary infection than their circumcised counterparts.[10]

During preschool and school age, the male-to-female ratio observed in neonates is reversed, making screening bacteriuria more prevalent in girls (Table 7.1).[8,9] In several large studies of school-aged children, the aggregate risk of screening bacteriuria has been reported to be 0.7%–1.95% of girls and 0.04%–0.2% of boys.[11–15] However, in as many as one-third of these children a prior history of UTI or voiding symptoms could be elicited (Table 7.2). Based on an average annual incidence figure of 0.4%, Kunin (1964) estimated that bacteriuria will develop in approximately 5% of girls prior to graduation from high school. Additional data collected by Kunin (1970) revealed that infection will recur in up to 80% of all school-aged white girls and 60% of black girls within 5 years.[11] It must also be considered that UTIs may be underdiagnosed in children thought to have infections from other sources. O'Brien et al. reported that 4% of children less than 5 years of age who were seen in primary care settings for acute illness met the criteria for UTI ($>10^5$ organisms) despite having alternate site infections.[16]

In a prospective population-based study of symptomatic UTIs in children living in Goteborg, Sweden, Winberg et al. estimated that the aggregate risk for symptomatic UTI up to age 11 was at least 3% for girls and 1.1% for boys.[17] In an update of a previous study, the incidence of culture-documented UTIs was twice as high as previously estimated, affecting 7.8% of girls and 1.6% of boys during the first 6 years of life.[18] To confirm these findings, Mårild and Jodal performed a retrospective population-based study of 41,000 children of Goteborg, Sweden.[19] The cumulative incidence rate of symptomatic UTIs was 6.6% for girls and 1.8% for boys. Pooled prevalence rates of UTI in febrile females ages 0–3, 3–6, 6–12, and >12 months was 7.5%, 5.7%, 8.3%, and 2.1%, respectively. Among febrile males ages 0–3 months old, the prevalence rates of UTI were 2.4% of those circumcised and 20.1% of those uncircumcised.[20] These data probably do not reflect an increasing incidence of UTIs since the publication of the earlier reports, but instead a greater detection rate. In all these epidemiologic studies, the incidence of febrile UTIs was greatest in infant boys and girls compared with children over 2 years of age. Gender differences in the incidence rates of first-time febrile and nonfebrile UTIs were most evident in children greater than 2 years old. Girls greater than 2 years old were much more likely to present with first-time UTI, both with and without fever, compared with their age-matched male counterparts (Table 7.3) (Figure 7.1a and b).

Once treated, infants with symptomatic urinary infections are at risk for recurrent infection (26%), usually in the first 3 months of follow-up. In older girls, the risk for

recurrence following symptomatic urinary infection is as high as 40%–60% within 18 months. This risk persists into adulthood.[8] In one study, 60 girls with childhood bacteriuria followed into adulthood (9- to 18-year follow-up) were compared with 38 nonbacteriuric controls.[21] During pregnancy, a significantly greater incidence of bacteriuria was diagnosed in the group with the history of positive urine cultures in childhood (63.8%) than in the controls (26.7%). Further evidence supporting a lifelong risk for symptomatic urinary infection in individuals presenting during childhood is reported by the Goteborg Childhood UTI Research Group. These authors followed 111 women with renal scarring or recurrent UTIs from their first UTI until adulthood, with a median follow-up time of 15 years. Febrile UTIs were more prevalent than nonfebrile UTIs during the first 10 years of life but continued to occur into the third decade. Although the prevalence of febrile UTIs diminished in adulthood, women with renal scarring during childhood were significantly more likely to have subsequent febrile UTIs. Overall, the median incidence of symptomatic UTIs was seven per individual.[22,23] As detailed later in the chapter, vesicoureteral reflux (VUR) increases susceptibility to acute pyelonephritis (APN) and perhaps even increases the risk for UTI, but only when the severity of VUR is so great that it promotes urinary stasis.

Evidence that heredity plays a role in determining individual susceptibility to UTI is accumulating. Family members of children prone to APN are reported to have a 15% incidence of APN, compared with only 3% of relatives of control subjects.[24] The daughters of mothers who had been bacteriuric in childhood show a higher incidence of UTI, and female siblings also tend to show a higher incidence of bacteriuria.[21,25] Children with first-time pyelonephritis significantly more often have relatives with a history of UTI than do controls.[26] Racially dependent differences in the prevalence of UTIs and in the rate of bacteriuria have also been reported. Kunin et al. (1964) reported a 1.2% bacteriuria prevalence rate in white girls versus a rate of 0.5% in black girls in the same age group. In a retrospective review, the number of black girls evaluated following UTI who were found to have VUR was one-third that of white girls at an institution where an equal number of black and white girls were hospitalized.[27] This observation was subsequently confirmed by a prospective study of patients admitted to this same institution with febrile UTIs.[7] Experimental UTI in mice is also significantly influenced by heredity, as evidenced by a slower response to treatment in certain strains of inbred mice compared with others that resolve the UTI more rapidly.[28] These same studies have also demonstrated that the acute inflammation and acquired immune response (antibody production) that follow urinary infection differ among genetically different strains of mice. As stated, "[this] result strongly suggests that the presence or absence of specific host genes will determine how effectively an *E. coli* UTI will be resolved."

There are likely genetic components that contribute to UTI susceptibility. While mice lacking the interleukin 8 (IL-8) receptor are more susceptible to APN than their wild-type counterparts, a similar increased risk for APN is seen in children with diminished chemokine receptor 1 (CXCR1) expression, which is homologous to the murine IL-8 receptor.[24]

There are also other groups of patients who are at higher risk for UTI-related morbidity and/or mortality. Specific examples include a higher risk for recurrent pyelonephritis, bacteremia, and allograph dysfunction in renal transplant patients who contract UTI within the first 3 months of transplantation. In spinal cord injury patients, the second most common cause of death is UTI.[29,30] Catheter-associated UTI is the most common nosocomial infection in hospitals in the United States and nursing homes, with an estimated aggregate cost of more than $600 million to our healthcare system.[31,32]

Bacteriology

Research has identified specific virulence factors that determine an organism's pathogenic potential, thus differentiating strains commonly associated with ABU, cystitis, or APN. Not all strains are capable of causing UTI. Uropathogenic *Escherichia coli* (UPEC) are specific subsets of extraintestinal pathogenic *E. coli* that possess specific virulence properties. Virulence factors that lead to infection include bacterial adherence, toxin production, motility, metal acquisition capacity, and the ability to evade host defenses.[33]

TABLE 7.3 Prevalence of UTI in girls <2 years old and boys <1 year old with respect to common demographic and clinical indicators

Note: Indicators in boldface type correlated significantly with the likelihood of diagnosing a UTI.
Abbreviation: CI, confidence interval.

A large family of gram-negative, aerobic bacilli known as Enterobacteriaciae cause the majority of uncomplicated UTIs. Included in this family are the species *Escherichia*, *Klebsiella*, *Enterobacter*, *Citrobacter*, *Proteus*, *Providencia*, *Morganella*, *Serratia*, and *Salmonella*. Of these, *E. coli* is by far the most frequently isolated organism, being responsible for approximately 80% of UTIs. This family of bacteria is generally characterized by a negative reaction to the oxidase test and the capacity to ferment glucose and reduce nitrates to nitrite. *Pseudomonas* is also a gram-negative, aerobic bacillus but is distinct and unrelated to Enterobacteriaciae. Most *Pseudomonas* recovered from the urine are of relatively low virulence and do not tend to invade tissue unless host defense mechanisms are compromised.

The most common gram-positive organisms found in UTIs are *Staphylococcus* and *Enterococcus*. Anaerobic

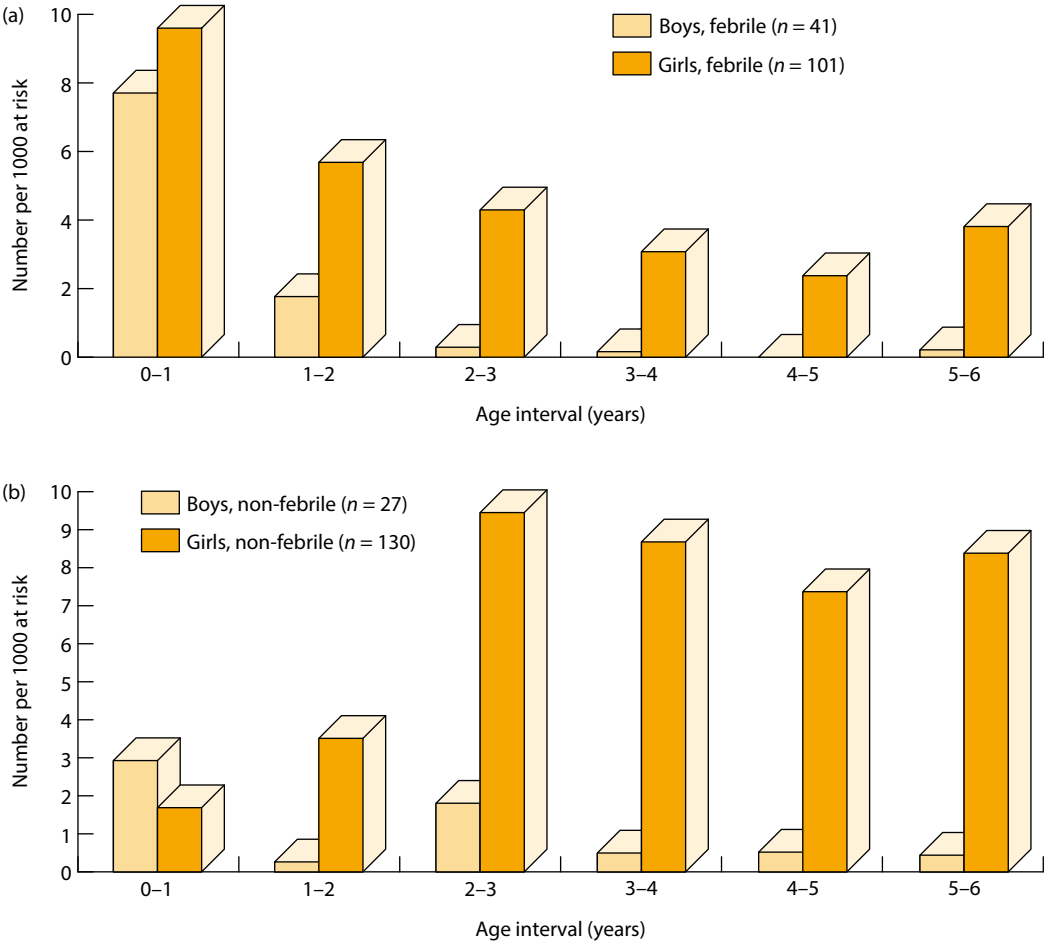

FIGURE 7.1 (a) Annual incidence rate in 1-year intervals of febrile UTI in children studied during a 20-month period between 1979 and 1981. (b) Annual incidence rate in 1-year intervals of nonfebrile UTI in children studied during a 20-month period between 1979 and 1981. (Adapted from Mårild S, Jodal U. *Acta Paediatr* 1998;87:549–52.)

fecal flora rarely produce UTIs despite being 100–1000 times more abundant than *E. coli* in stool.[34] Occasionally, unusual or fastidious organisms may produce infections that are difficult to detect because they do not grow well in commonly used culture media. For example, *Haemophilus influenzae* has been reported to cause urinary infections, as well as epididymo-orchitis in infant males.[35,36] Other unusual organisms include *Salmonella* sp. and *Shigella*. Although lactobacilli, corynebacteria, and α-*Streptococcus* may rarely cause UTI, they probably should be considered contaminants unless they are found in the culture of specimens obtained by SPA or catheterization.

The bacteriological findings in the Goteborg study suggest that "the [predisposing] environmental conditions in the periurethral region and the host defense mechanisms vary with age and sex."[17] This study identified four characteristic bacteriologic trends in childhood UTIs:

1. A high frequency of *Proteus* sp. infections in older boys (most of whom were uncircumcised), and greater variability in infecting organisms in boys than in girls
2. A greater likelihood of staphylococcal infection in adolescence, especially in girls
3. A greater frequency of *E. coli* urinary infection in neonatal boys than in girls of that age
4. A decreased frequency of *Klebsiella* urinary infection in older children (Table 7.4)

Other general rules include the fact that the majority of uncomplicated infections are caused by a single organism. Patients with complicated infections, particularly those children who have been managed with long-term catheterization, may have multiple organisms. Sometimes the strain of bacterium is suggestive of underlying urinary pathology, such as the relationship of *Proteus* sp. and struvite stones.

Serology

E. coli, the most common species of uropathogens, can be typed serologically by three major groups of antigenic structures capable of producing specific antibodies. There are more than 150 O (cell wall) antigens, more than 50 H (flagellar) antigens, and approximately 100 K (capsular) antigens. Not all strains are typable. Serological classification in UTI is restricted mainly to O antigens. Early studies have attempted to correlate serological markers with increased virulence or tissue invasiveness. Most of these were epidemiological studies that were conducted prior

to discovery of the special role of specific virulence factors, such as adhesins (attachment structures). In contrast to patients with cystitis or ABU, patients with pyelonephritis have been found to be more frequently infected with certain O typable strains and strains having certain K antigens. Eight O antigen types (O1, O2, O4, O6, O7, O18, O25, and O75) were the cause of 80% of cases of pyelonephritis in one report. Another study reported that *E. coli* possessing five K antigens (K1, K2, K3, K12, and K13) accounted for 70% of isolates from patients with pyelonephritis.[37] These earlier serologic studies have been extended to identify more specific O:K:H combination serotypes characteristic of pyelonephritogenic strains. However, specific attachment structures appear to be the more important determinants of disease severity and of the likelihood of postpyelonephritic renal scarring.

Bacterial Virulence Factors

The term *virulence* simply refers to the ability of microorganisms to cause disease. The concept of uropathogenic bacteria refers to certain strains that are selected from the fecal flora, not by chance or prevalence, but because of the presence of specific virulence factors that enhance colonization of the uroepithelium. Other virulence factors aid in the persistence of bacteria in the urinary tract and provide these organisms with the capacity to induce inflammation of the urethra, bladder, or renal parenchyma. The following information will include known data detailing specific *E. coli* virulence factors. Advancements in technology continually increase our knowledge of how bacteria propagate and survive.[38]

Adherence

Bacterial adherence or attachment is an essential initiating step in all infections. Perineal colonization by uropathogenic bacteria has been found to precede clinical UTI in women and children at risk for UTI.[6,39–42] Tissue invasion, inflammation, and cell damage are secondary events. Utilizing specialized structures (adhesins), uropathogenic bacteria, especially *E. coli*, can attach to specific receptor sites on the uroepithelium and can also bind in a nonspecific manner by electrostatic and hydrophobic factors. By virtue of such attachment, virulent strains of bacteria can ascend into the upper urinary tract even in the absence of structural abnormalities, such as VUR.

Specific attachment (bacterial tropism) to uroepithelial cells is mediated by adhesins localized either in an outer coat of capsule or on specialized structures. Fimbrial gene clusters (type 1, P, F1c, Dr, Auf, S, and M) or operons encode all the genes necessary for fimbriae assembly.[33] Collectively known as fimbria, these attachment structures are capable of recognizing and attaching to receptors located on uroepithelial cells and to some constituents of the basement membrane. Type 1 fimbria mediates agglutination between bacteria and cells in culture. Since this agglutination can be competitively inhibited by a mannose-rich solution, these fimbriae are therefore termed mannose sensitive. Other fimbriae attach to uroepithelial cells in the presence of soluble mannose and are termed mannose resistant (Figure 7.2). Uropathogenic bacteria rely on both mannose-sensitive type 1 fimbria and mannose-resistant type 2 fimbria (also termed P-fimbria) to colonize the urinary tract. In addition to type 1 and P-fimbria, uropathogenic bacteria employ several other adhesins, both fimbrial and nonfimbrial. Unfortunately, little epidemiological evidence exists that clarifies the role of these additional adhesins on *E. coli* (S-fimbria, FIC-fimbria, and S/FIC-related fimbria), *Klebsiella* (MR/K HA), and *Proteus* sp. (MR/P HA, PMF, ATF, NAF, and UCA) in the pathogenesis of UTI.

In addition to promoting attachment, type 1 fimbriae mediate bacterial invasion into the uroepithelial cells themselves, thus protecting bacteria from antibiotics that do not penetrate the cell's membrane, such as aminoglycosides.[43] In fact, viable internalized bacteria can be isolated from uroepithelial cells 48 hours after infection, and may account for recurrent infection by the same bacterial strain (Figure 7.3). Once type 1–fimbriated *E. coli* attach, the uroepithelial cells undergo apoptosis (programmed cell death) that results in bladder mucosal ulceration.

Although the entire urothelial surface, including the upper urinary tract, contains glycoprotein receptors for type 1 fimbria, no evidence exists that implicates type 1 fimbria directly in the pathogenesis of pyelonephritis. However, it

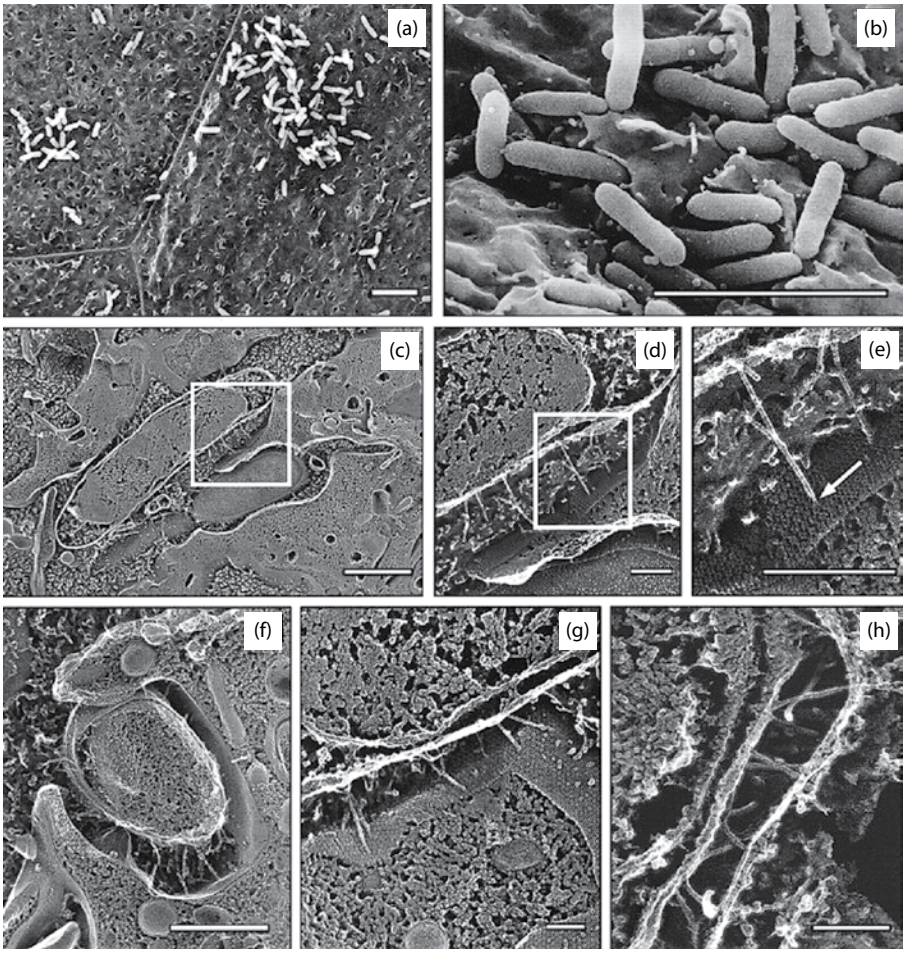

FIGURE 7.2 Type 1 pilus-mediated bacterial adherence to the bladder epithelium. Mouse bladders were processed for (a, b) scanning electron microscopy (SEM) and high-resolution EM at 2 h after infection with *E. coli* NU14. The boxed areas in (c) and (d) are shown magnified in (d) and (e), respectively. The arrow in (e) indicates the FimH-containing tip. In (h), type 1 pili span from the host cell membrane on the right to the bacterium on the left. Scale bars = 5 μm (a, b), 0.5 μm (c, f), and 0.1 μm (d–h). (From Mulvey MA et al. *Science* 1998;282:1494–7.)

has been demonstrated in experimental models and clinical studies that once pyelonephritis occurs, the presence of type 1 fimbria significantly increases a strain's ability to persist in the urinary tract and to stimulate inflammation.[44–46]

Clinical and experimental studies have shown that pyelonephritic *E. coli* frequently possess fimbriae that can recognize and agglutinate erythrocytes of the P1-blood group. Hence, this type of pili has been termed P-fimbria. The P-fimbriae are mannose-resistant adhesins that attach to the carbohydrate portion (α-D-galactopyranosyl-(1–4)-β-D-galactopyranoside) of the glycolipid antigen in the P-blood group series, which is also expressed by human uroepithelial cells.[47,48] The components of P-fimbria are encoded by 11 genes in the pap gene cluster, of which pap E, F, and G encode for the adhesin subunits.

Further research has identified that not all P-fimbriae are alike. Proteins located at the tip (G-tip proteins, or tip adhesins) determine the fimbria's specific attachment properties. Three classes have been identified, of which only class II and class III P-fimbriae have uropathogenic potential. In vitro studies have found that the class III P-fimbriae bind receptors found in higher density on bladder uroepithelium. In contrast, class II tip adhesins may be more important in the evolution of APN by virtue of an increased density of class II–specific receptors located on the uroepithelium of the upper urinary tract.[49] Roberts et al. have recently described a statistically significant greater likelihood of clinical and histologic indicators of APN in primates inoculated with class II–fimbriated *E. coli* than when primates are inoculated with class III–fimbriated *E. coli*.[50]

Epidemiological studies in children have provided considerable evidence that the presence of P-fimbriae on *E. coli* is a significant virulence factor, particularly in upper UTIs. These studies have shown that 76%–94% of pyelonephritogenic strains of *E. coli* are P-fimbriated compared with 19%–23% of cystitis strains, 14%–18% of strains isolated from patients with ABU, and 7%–16% of fecal isolate strains.[38,51] Other evidence supporting the importance of P-fimbria in causing upper UTIs comes from animal model studies. Inoculation of the bladders of nonrefluxing primates with P-fimbriated *E. coli* resulted in pyelonephritis in 66% of animals. In contrast, pyelonephritis was not seen in any of the monkeys inoculated with non-P-fimbriated *E. coli*.[52]

In addition to its role in the pathogenesis of pyelonephritis through attachment to renal epithelial cells,

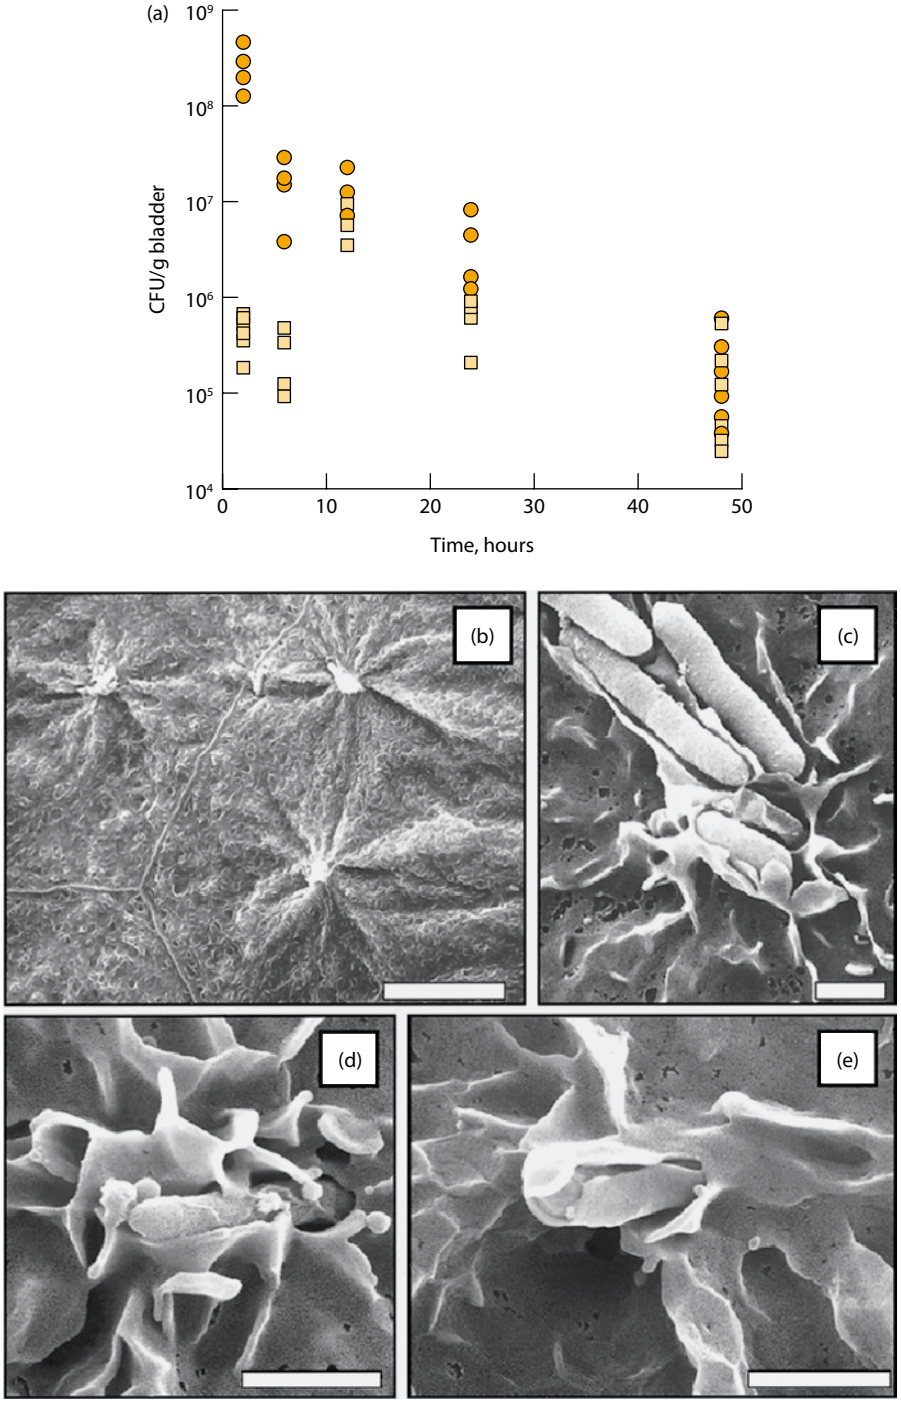

FIGURE 7.3 Kinetics of bacterial reduction in *E. coli* NU14-infected bladders and the persistence of intracellular bacteria. (a) The total numbers of bacteria per gram of mouse bladder (circles) and the numbers of gentamicin-protected bacteria (boxes) were examined per time point. (b–e) Bacteria in various stages of internalization into superficial cells at 2 h after infection with *E. coli* NU14 were detected by scanning electron microscopy (SEM). Scale bars = 10 μm (b) and 1 μm (c–e). (From Mulvey MA et al. *Science* 1998;282:1494–7.)

P-fimbriae also function to promote intestinal carriage by the host, as well as enhancing perineal colonization (see host factors) and persistence in the urinary tract. Although the data regarding intestinal carriage and perineal colonization (see host factors) by P-fimbriated *E. coli* strongly implicate the P-fimbria in the pathogenesis of infection, the data regarding bacterial persistence are less clear.

Although fimbriae appear to be the primary method by which bacteria colonize the urinary tract, there is also attachment to nonexposed ligands located in the interstitium. Dr family adhesins are surface structures that bind to bladder epithelium and type IV collagen on basement membranes. They are associated with cell invasion in vitro and contribute to pathogenesis in animal models.[53,54]

UpaG is a nonfimbrial adhesin autotransporter that promotes cell aggregation and the formation of biofilms, and mediates adhesion to human bladder epithelial cells.[55] Secondary binding to fibronectin occurs by means of fimbria encoded by pap, papG, sfa, afa, and prsG DNA sequences, a feature also more common in pyelonephritogenic strains than in strains causing cystitis or ABU.[56,57] Other adhesins may actually play a protective role by preventing UTI through competitive binding. For example, S-fimbria and type 1 fimbria bind to the Tamm–Horsfall protein and low-molecular-weight substances, respectively. Once bound, clearance of bacteria by periodic shedding of these soluble bacteria–protein complexes in the urine offers a theoretical advantage by reducing the number of infecting organisms.

Some data suggest that an organism's phenotype is variable, first facilitating colonization of the uroepithelium, and then undergoing specific changes to evade eradication by the host's immune response.[58] For example, some type 1 bacteria do reach the renal parenchyma (as in the case of VUR). These bacteria, however, must then escape type 1 fimbria-specific neutrophil receptors. In vitro studies have demonstrated that neutrophils elicit a more severe inflammatory response in the presence of type 1–fimbriated strains than when in the presence of a mutant strain lacking the type 1 fimbria.[45] Phase variation to non–type 1–fimbriated strains is known to occur, thereby conferring a potentially protective advantage. Despite this apparently unified view of bacterial virulence, several studies also exist to challenge any attempt to simplify the complex interaction between bacteria and host.[59,60] In fact, the appearance of P-fimbriated strains in the periurethral region of girls at risk for cystitis does not inevitably result in urinary infection.[61] Thus, bacterial virulence properties should not be the sole focus of blame in the development of UTI. Host risk factors probably are of equal, if not greater, significance.

Despite its significance, bacterial adherence is only one of several factors believed to have a role in infection. Other bacterial virulence factors and host defense factors may play an even greater role in tissue invasion and inflammation. In an experimental study in mice, the presence of P-fimbriae was necessary for colonization of the upper urinary tract but did not produce tissue invasion unless combined with other virulence factors.[62] Similarly, in a clinical study that employed dimercaptosuccinic acid (DMSA) renal scans to document acute inflammatory parenchymal damage in children with febrile UTI, no difference in the prevalence of P-fimbriated *E. coli* was found in children with an abnormal scan compared with those who had a normal scan.[63] Likewise, renal scarring has been reported to be more common following pyelonephritis caused by non–*E. coli* organisms when compared with those caused by P-fimbriated *E. coli*.[64,65]

Other Virulence Factors

Endotoxin: A lipolysaccharide present in the bacterium's cell wall, endotoxin is responsible for initiating the acute inflammatory response common to gram-negative infections. This same inflammatory response that eradicates the bacteria probably also leads to postpyelonephritic scarring.

Cytotoxic necrotizing factor 1 (CNF-1): CNF-1, secreted by some strains of bacteria as they invade the uropethilial cell, binds to members of the Rho family of GTP binding proteins (Rho, Rac, and Cdc42), resulting in cytoskeleton rearrangements in host cells, as well as modifications to uroepithelial cell apoptotic processes, that appear to permit bacterial invasion and permanence in the urinary tract.[66] It has been demonstrated that the antiapoptotic property of CNF-1 is dependent on the Rac-induced activation of the phosphoinositide 3-kinase (PI3K) pathway and the Bcl-2-dependent remodeling of the mitochondrial network in epithelial cells.[67] Thus, CNF-1 appears to facilitate bacterial persistence within the uroepithelial cells by opposing the natural tendency of uroepithelial cells to apoptose once infected. Therefore, CNF-1 is a fitness factor for infection, not a requirement.[68]

Hemolysin: Hemolysin is another recognized virulence property capable of damaging renal tubular cells, in vitro. Encoded by the hlyCABD operon, hemolysin stimulates cytokine production and leads to an inflammatory response that contributes to epithelial damage and bladder hemorrhage in vivo and is implicated in causing renal damage and increasing risk for septicemia.[69] Hemolytic strains of *E. coli* produce more severe experimental pyelonephritis in mice.[70]

K antigen: Capsular polysaccharides afford K antigen specificity to *E. coli*. K antigen has been shown to shield bacteria from complement lysis and phagocytosis and to enhance persistence of bacteria in the kidneys of experimental mice.[71–75] It is more commonly isolated from children with clinical pyelonephritis than from children with cystitis or healthy controls.[37,73–75]

Colicin: Another protein elaborated by pyelonephritogenic *E. coli*, colicin kills other bacteria in the vicinity of the *E. coli* producing it.[70] The *colicin V plasmid* is also thought to encode for an iron uptake system that further promotes the survival and pathogenicity of colicin-producing organisms.[76]

Metal binding capacity: Most bacteria require iron for optimal growth and metabolism and have developed mechanisms to acquire iron when there is limited supply. Mediated by such proteins as *aerobactin*, the iron binding capacity has also been shown to be associated with increased virulence in epidemiological studies.[77,78] In one study, UPECs were found to have greater than 10 characterized uptake systems and transporters for acquiring iron.[79] Additional metal binding capacity is an important virulence factor as well. Uptake of heme, enterobactin, and other sidophores also helps contribute to bacterial fitness.[80] Recently, zinc acquisition via high-affinity zinc transport systems such as ZnuACB was shown to contribute to the virulence of *E. coli*.[81]

Serum resistance: In the presence of fresh human serum, many strains of *E. coli* are killed following activation of complement. Serum resistance to such killing action is another property that has been related to virulence of gram-negative bacteria both in UTIs and gram-negative bacteria.[82]

Flagella-mediated motility: Motility is mediated by complex surface structures called flagella and is another trait associated with bacterial fitness.[83] Flagella genes are poorly expressed during chronic UPEC infection in mice,

and the synthesis of flagella appears to be tightly regulated and coincides with ascension of the bacteria.[84]

Intracellular bacterial communities (IBCs): Experimentally infected mouse bladders and voided uroepithelial cell collections from humans have been used to identify IBCs. These represent clonal invasion of bladder epithelial cells that thereby protect the bacteria from both the host immune response, including neutrophils, and antibiotics. It is hypothesized that the IBCs and quiescent intracellular reservoirs might contribute to antimicrobial resistance and recurrence of UTI.[85]

Other virulence properties enhance the bacteria's ability to evade the host immune response. For example, host protein lipocalin 2, which is expressed and released by neutrophils, binds to and sequesters enterobactin, which is a necessary iron source for UPEC.[86] However, UPEC is capable of modifying enterobactin by glycosylation into salmochelin, which is not recognized and sequestered by lipocalin 2, therefore evading the host defense.[87] Some strains of *E. coli* synthesize factors that inhibit cytokine responses, enhance tolerance to reactive oxygen and nitrogen species, and encode proteins that suppress the host inflammatory response during early stages of infection.[88–93]

Role of Bacterial Virulence in Renal Scarring

Regardless of their role in the etiology of UTI, some studies suggest that there may be a paradoxical relationship between bacterial virulence, defined by P-fimbriated binding, and renal scarring. In one study of patients with recurrent pyelonephritis, virulent clones expressing P-fimbria occurred significantly less often in patients who developed scarring (22%) than in those who did not develop renal scars (62%).[49] Although the frequency of scarring among girls with VUR was 57%, in contrast to 8% of those without reflux, this alone did not explain the selection of bacteria of low virulence in those patients with scar development. Lomberg et al. concluded that reduced host resistance was essential for the tendency of renal scarring after APN.

Other evidence supports the hypothesis that bacteria with greater virulent potential, as measured by the presence of adhesins, may elicit a more rigorous inflammatory response than less virulent clones and are thus cleared more rapidly. An alternative explanation would be that children infected with more virulent bacteria present earlier with symptoms, such as fever, resulting in more prompt diagnosis and treatment. Observations in patients with bladder dysfunction and ABU have demonstrated a low prevalence of P-fimbriated *E. coli* (less than 20%), suggesting that the presence of specific attachment structures may not be necessary for bacterial persistence in the urinary tract.[72,94,95] Moreover, coincident with an inflammatory response, P- and type 1–fimbriated *E. coli* were demonstrated to be cleared more rapidly than nonfimbriated strains from individuals with bladder abnormalities.[96]

Although these virulence factors have been considered separately, their effects appear to be additive. In contrast to those with cystitis or ABU, the majority of bacterial isolates in patients with nonreflux APN express three or four virulence properties.[49] Interestingly, the frequency of P-fimbriae and other virulence factors is significantly lower in patients who have VUR. This would appear logical since, in the presence of reflux, virulence properties, such as adherence, are not necessary for bacteria to reach the upper urinary tract. It has been suggested that efforts aimed at interfering with "virulent" bacteria, such as by vaccination, may be of less value in patients with recurrent pyelonephritis and reflux, the group in whom renal scars are more likely to develop. However, others have not demonstrated a significant difference in virulence traits among pyelonephritogenic strains in patients with and without reflux.[97]

Molecular Host Defense Factors

Interacting with bacterial virulence properties are an equally important and complex number of mechanical, hydrodynamic, antiadherence, receptor-dependent, and immunologic host factors that affect an individual's susceptibility to UTI.

Antiadherence

Epidemiological and in vitro data confirm that some blood group antigens behave as bacterial receptors in addition to their long-recognized role in determining red cell phenotypes. Of the many carbohydrate antigens, the role of ABH, Lewis antigens (Le^a, Le^b, Le^x, and Le^h), P, Kell, Duffy, MNS, and Kidd systems in host susceptibility to urinary infection is now better understood. Blood group antigens can be found on the surfaces of many epithelial cells in the body, including vaginal and uroepithelial cells, and as secreted antigens in mucus, in addition to on erythrocytes.[98,99] Presumably, bacterial colonization of epithelial surfaces is facilitated by cell surface–bound antigens, while secreted antigens mitigate colonization by virtue of competitive inhibition.

Individuals belong to one of two distinct phenotypes based on the expression of ABH and Lewis antigens on cell surfaces and in secretions (Table 7.5). The secretor phenotype is characterized by ABH antigens in saliva, Le^b and Le^y antigens on epithelial cell surfaces, and Le(a–b+) erythrocytes. Nonsecretors have mucus devoid of ABH antigens, express Le^a and Le^x antigens on epithelial cells, and have Le(a+b–) erythrocytes. Those with Le(a–b–) erythrocytes can be secretors or nonsecretors, depending on the presence of ABH antigens in secretions.

Since bacterial attachment to glycoprotein (type 1 fimbria) or glycolipid (P-fimbria) receptors is critical to colonization and tissue invasion, respectively, an individual's risk for UTI may be influenced by the composition of surface receptors available for bacterial attachment. Observations

TABLE 7.5 Distribution of antigens in secretions and on epithelial cells and erythrocytes in the secretor and nonsecretor phenotypes

	Secretor	Nonsecretor
Secretions (saliva, mucus)	ABH antigens	No ABH antigens
Epithelial cells	Le^{b+}, Le^{y+}	Le^{a+}, Le^{x+}
Erythrocytes	Le^{a-}, Le^{b+} Le^{a-}, Le^{b-}	Le^{a+}, Le^{b-} Le^{a-}, Le^{b-}

by Schaeffer and coworkers in healthy women found that the profile of antigen expression on vaginal cells and in vaginal mucus correlated with the ABO phenotype and secretor status.[100] They also noted that individuals within the same blood group phenotype expressed different amounts of ABH and Lewis antigens. Moreover, longitudinal analysis demonstrated that the level of expression of these antigens fluctuated over time.[101] However, utilizing quantitative immunohistochemical techniques, Schaeffer's group did not identify an association between a particular phenotype and a positive history of UTI when controlling for secretor status.[102] Thus, despite the appealing hypothesis that some individuals may be more susceptible to bacterial colonization by virtue of genetically determined cell surface antigens, these data do not support this notion in adult women.

In children, similar associations between blood group phenotypes and the risk of UTI have been sought. Sheinfeld et al. studied the expression pattern of blood group antigens in 72 tissue specimens from children who underwent surgery for anatomic abnormalities of the urinary tract.[103] Sixty-six percent (48/72) had a history of UTI, and the remainder served as controls. Although an increased susceptibility to UTI was noted among nonsecretors compared with secretors, the high risk of UTI was most likely a consequence of the prevalence of structural abnormalities in this study population.[103] Jantausch et al. performed a more extensive analysis of blood group antigens in seven different systems and found that only the Le(a–b–) phenotype correlated with a positive history of febrile UTIs in children, yielding a threefold relative risk.[103,104] Recently, Albarus et al. sought to confirm the association between blood group phenotypes and the susceptibility to childhood febrile UTIs. In a well-matched case-control study of children with a febrile UTI during the first year of life, no such association existed.[105] If blood group phenotypes and secretor status do not influence the risk of UTI, as some data might suggest, then perhaps the susceptibility to UTI is mediated by urinary or epithelial factors that are as yet unidentified.

Urinary Inhibitors

Although urine commonly provides the appropriate environmental conditions for successful bacterial growth, several constituents within urine have been identified that inhibit bacterial growth. Normally, the pH of urine fluctuates between 4.6 and 7.2 in accordance with physiologic needs. Since the optimal pH range for bacterial growth is between 6 and 7, increases in urine acidity can limit bacterial growth. Extremes of urine osmolarity can also inhibit bacterial growth by virtue of the limited nutrients available to support replication in dilute urine (hypo-osmolarity) or from the dehydration that ensues in concentrated urine (hyperosmolarity). Additional studies have identified short, positively charged peptides, β-defensin 1 and cathelicidin LL-137, that are antimicrobial peptides, which are protective against UTI.[105–107] Specifically, mechanistic studies in the murine model suggest that these antibacterial peptides play an important role in the bladder mucosa's ability to clear bacteria.[106,108]

The Tamm–Horsfall protein, a glycoprotein secreted by luminal cells of the ascending loop of Henle, may also be protective. This glycoprotein has been shown to contain abundant mannose residues and is identical to uromucoid. In vitro studies have shown adherence of large numbers of *E. coli* with type 1 fimbria to uroepithelial cells coated with uromucoid, in contrast to poor adherence to uroepithelial cells devoid of uromucoid.[109,110] The Tamm–Horsfall protein, when secreted into human urine, will bind to type 1 fimbriae, limiting the interaction of UPEC with host uroepithelial receptors. In fact, two studies have demonstrated such binding between type 1 and S-fimbria and the Tamm–Horsfall protein.[111,112] The Tamm–Horsfall protein has also been demonstrated to bind to neutrophils, and it is believed that this interaction can mediate recognition of bacterial invasion by neutrophils.[113] A study of UTIs in infants revealed a significantly lower mean concentration of the Tamm–Horsfall protein in those with documented *E. coli* infections compared with healthy controls.[114]

Receptors

Bacterial adherence, particularly by P-fimbria on certain strains of *E. coli*, appears to be particularly significant in the pathogenesis of upper UTIs. As discussed earlier, a special class of glycosphingolipids, possessing Gal 1–4 Gal oligosaccharide, act as receptors for p-fimbriated *E. coli*.[47,48] These receptors are antigens in the P-blood group system. It is felt that host susceptibility to bacterial adherence is conferred by the P1-blood group phenotype, since this group is overrepresented in children with recurrent pyelonephritis in contrast with normal controls.[115,116] However, this overrepresentation of the P1-blood group phenotype is seen only in patients with pyelonephritis who do not have associated VUR.[116] Despite the tenuous association between nonsecretor status and an increased susceptibility to UTI, apparently as a result of diminished secretion of antiadherence factors, a recent study has identified the presence of specific attachment structures for *E. coli* in nonsecretors. Stapleton et al. have identified glycosphingolipids on vaginal and renal epithelial cells that bind each of the three major classes of *E. coli* adhesins. Of the glycosphingolipids studies, sialosyl galactosyl globoside was determined to be the preferred binding receptor for UPEC.[117] Thus, an individual's risk for UTI may be more strongly influenced by the presence of receptors for bacterial attachment, rather than the absence of blocking antigens.

Patients who are prone to UTIs seem to have higher numbers of receptors for bacterial fimbriae.[118] CXCR1 is the receptor for IL-8 and is essential for the migration and activation of neutrophils. It has been demonstrated that the CXCR1 mRNA and protein levels are significantly lower in children who are prone to pyelonephritis.[119] Supporting evidence showed that UTI-prone children had single-nucleotide polymorphisms in their CXCR1 genes when compared with pediatric control patients, confirming a genetic influence for some at-risk children.[120]

Innate Immunity

The immunologic response to UTI has been studied at both the kidney and bladder level. Understanding the immune response to infection is particularly important

because immunization is currently being explored as a possible means of preventing recurrent UTIs. Innate immune responses are induced or mediated by pattern recognition receptors, antimicrobial peptides, and neutrophils. The antibody response to infection has also been used diagnostically to localize the level of urinary infection to the upper or lower urinary tract.[121,122]

Antibody Response

The focus of most of the clinical and experimental immunologic studies of UTI has been the immune response to pyelonephritis. During APN, a systemic antibody response occurs, with antibody production primarily against the O antigen of the infecting bacteria. A diminished response is seen toward the K antigen.[37,123,124] Counteracting bacterial adherence to host epithelial cells are protective antibodies that may be passively acquired (from mother to fetus) or actively acquired through previous exposure to infection. Conversely, in the absence of protective antibodies, some individuals are at greater risk for UTI.[125] Antibodies of the immunoglobulin M (IgM), IgG, IgA, and secretory IgA type have all been demonstrated in the serum and urine of children and experimental animals with APN.[126,127] High IgG, IgA, and secretory IgA antibody levels have also been found in the urine of girls with pyelonephritis.[127] The presence of antibodies within the renal parenchyma enhances bacterial opsonization, the process by which bacteria are coated by proteins that lead to further phagocytosis.

An antibody response to pili has also been found following pyelonephritis.[128] Secretory IgA directed against pili has been recovered from the urine of patients with APN and has been shown to prevent in vitro adherence of *E. coli* to human uroepithelial cells.[129] Mannose-specific interactions between *E. coli* and the carbohydrate moiety of secretory IgA have been reported.[130] Secretory IgA, when bound to the uroepithelium, may thus offer a receptor site for bacteria. When excreted, it may result in competitive inhibition of binding.

With regard to the immune response of the bladder to urinary infection, a systemic circulating antibody response to cystitis is not seen.[127,131] However, an elevation of secretory IgA antibody in the urine has been observed in children with UTI, suggesting local antibody production.[127,132] A more recent study reported a decreased excretion rate of secretory IgA in uninfected children with a history of symptomatic infections compared with healthy controls. However, when these girls were subsequently studied at the time of symptomatic UTI, secretory IgA excretion rates were significantly higher than in controls.[133] Other evidence supporting a role for secretory IgA as a host defense factor comes from animal studies. Attempts at local immunization of the urinary tract have shown that intravesical immunization is effective against experimentally induced ascending UTI in rats.[134] The presence of secretory IgA in the urine following local bladder or vaginal immunization has been shown to decrease adherence to uroepithelial cells in this experimental model.[135,136]

The urine of newborns has nearly undetectable levels of secretory immunoglobulin A (sIgA) that increase during the first year of life, particularly in breast-fed as compared with non-breast-fed infants. Case-control studies have identified a diminished incidence of UTI in breast-fed infants, presumably related to soluble substances that are absorbed enterically and excreted into the urine. Using high-performance liquid chromatography to purify oligosaccharides in breast milk, Coppa et al. identified small-molecular-weight, neutral oligosaccharides that significantly decreased adhesion between human uroepithelial cells and *E. coli* isolated from an infant with UTI.[137] Additionally, breast milk contains T and B lymphocytes, cytokines, growth factors, and most importantly, antibodies that may act synergistically to decrease the breast-fed infant's risk of UTI.

No differences have been noted in the levels of urinary sIgA among boys and girls, and thus impaired immunity does not explain the higher incidence of UTI in infant boys compared with girls. Instead, the predominance of UTI in infant boys likely reflects local periurethral factors (especially among uncircumcised boys).[50]

Cell-Mediated Immunity

The protective role, if any, of cell-mediated immunity in UTI is controversial.[138] A T and B lymphocytic response is seen in the kidney during experimental pyelonephritis.[139] However, others have shown a depressed cell-mediated response during the early phase of renal infection when bacterial replication is maximal.[140] Although such studies have documented cell-mediated host responsiveness to bacterial infection, they have not defined the role of this process in the pathogenesis of UTI. There is no strong clinical evidence to support abnormality of cell-mediated immunity in patients prone to UTI. Experimental UTI in mice has demonstrated no increased susceptibility to *E. coli* in athymic animals (with dysfunctional cellular immune systems) and normal controls.[141] Similarly, in patients with compromised immune systems, an increased susceptibility to UTIs has not been reported. Studies to better define the role of the immune response in UTI are obviously needed.

Further evidence supports a role for the uroepithelial cell in immunity against uropathogenic bacteria. Normally, uroepithelial cells have the capacity to produce cytokines when exposed to bacteria in vivo and in cell culture systems. While some cytokines are secreted to serve as chemoattractants for inflammatory cells, others are not secreted and may play a role in the uroepithelial cells' inherent response to invasion by pathogenic bacteria (Table 7.6).

The specific stimulus for uroepithelial cell cytokine production and release appears to be components of P- and type 1 fimbria, since urinary levels of IL-6 are significantly

TABLE 7.6 Cytokine production by uroepithelial cells in the presence of uropathogenic bacteria

Cytokine	Secreted into the urine?
IL-1-α	No
IL-1-β	No
Tumor necrosis factor	No
IL-6	Yes
IL-8	Yes

greater in the presence of adhering bacteria and adhesin-positive P-fimbria.[142–144] Further in vitro studies have determined that in response to direct contact between bacterial fimbria and receptors located on the uroepithelial cell membrane, the uroepithelial cell is able to suppress bacterial growth.[145] Moreover, utilizing human uroepithelial cells in culture, Mannhardt and coworkers have demonstrated that, in individuals with a history of recurrent UTIs, a transmembrane defect impedes signal transduction within the urothelial cell, thus rendering the cell incapable of responding to bacterial attachment. These data lend support to the concept that the most important arm of cellular immunity in the urinary tract may not be T and B cells, as classically described, but instead the inherent ability of the uroepithelium to respond to bacterial invasion. The superficial layer of umbrella cells in the bladder is covered with membrane proteins known as uroplakins.[146,147] Uroplakin 1a triggers exfoliation of the bladder epithelium when stimulated by type 1 fimbriae. This exfoliation, which removes adherent bacteria, is a result of an apoptosis-like mechanism promoted by FimH.[148]

Neutrophils are the most rapid and robust responders to UTI. IL-8 is the main neutrophil attractant in humans, and studies have demonstrated its secretion by both bladder and kidney cell lines in response to UPEC.[119,149–151] In a murine model of UTI, Lundstedt et al. showed that mice lacking the murine interleukin IL-8 receptor homologue developed APN with bacteremia and renal scarring, whereas those with the intact gene did not.[119,152,153] Failure to properly activate neutrophils in the knockout mice resulted in impaired migration of neutrophils from the subepithelial space into the collecting system, termed neutrophil entrapment.[154] Recent clinical studies found significantly reduced expression of the human IL-8 receptor CXCR1 among APN-prone children compared with age-matched control subjects without UTI, suggesting that inherited genetic variants may predispose to infection.[119]

Transmembrane Signaling

Toll-like receptors (TLRs) are part of the innate defenses enabling hosts to eliminate pathogens that would lead to disease. The TLR structure is well conserved throughout evolution, and their structure and function are tightly regulated.[155] Structural variation is relatively rare, and much work is being done to identify which variations result in disease susceptibility. Thirteen TLRs have been identified in human and mouse together, with TLR10 being active in humans but not mice, while TLR11, TLR12, and TLR13 are present in mice but not humans. Among these, TLR4 has received the most recognition for its role in activating innate immunity when in the presence of gram-negative bacteria. It has been shown that TLR4 signaling can be induced by multiple mechanisms, including a P-fimbria-dependent and lipopolysaccharide-independent pathway and a lipopolysaccharide-dependent and type 1 fimbria-dependent pathway.[143,150,156] FimH can also directly interact with TRL4; however, independent of the source of stimulation, TLR4-mediated signaling results in the activation of NFκB and expression of IL-6 and IL-8.[157,158] Other TLRs utilize alternate sources for stimulation. TLR5 will produce proinflammatory factors as a result of recognition of UPEC flagella.[159] Together, these signaling receptors help with the recruitment of neutrophils to the uroepithelium.

TLR4 knockout mice develop ABU rather than severe infection, which led Ragnarsdóttir et al. to hypothesize that reduced mucosal TLR4 function may protect against symptomatic infection.[160] After sequencing the TRL4 promoter in Swedish blood donors and children with mild or severe susceptibility to UTI, they then performed a case-control study of pediatric patients with symptomatic bacteriuria or those prone to recurrent APN. The results showed that compared with symptomatic patients and healthy controls, ABU patients had fewer genotype patterns and their promoter sequence variants decreased TLR4 expression in response to infection. They concluded that genetic variation in the TLR4 promoter may be a largely overlooked mechanism to influence TLR4 expression and UTI susceptibility.[160] Additional studies demonstrated that children with asymptomatic infections have lower expression of TLR4 mRNA and protein in neutrophils than age-matched controls.[161]

Vaccines

Much of the significance of clarifying the immune response to UTI relates to the possibility of developing an effective vaccine to prevent urinary infections. Protection against experimental ascending pyelonephritis in rats has been demonstrated using isolated capsular antigen to stimulate antibody production directed at K antigen.[134] Similarly, immunization with *E. coli* P-fimbria in both mice and primates confers protection against ascending pyelonephritis, presumably by interfering with adherence of the organism to the uroepithelium.[162,163] Immunization of rats with purified type 1 fimbria also affords substantial protection against experimental ascending pyelonephritis.[164] Thankavel et al. have identified the specific subunit region within the FimH determinant of type 1 fimbria that is responsible for attachment to uroepithelial cells. Antibodies directed specifically against this region of only 25 amino acids, and no other regions on FimH or FimA subunits of type 1 fimbria, reduced experimental pyelonephritis in mice.[165] Some evidence suggests a potential role for immunization with hemolysins as well.[62] Historically, vaccines have been directed at known virulence factors, such as those listed above. More recent advances have been identified via genomic, proteomic, and metabolic screens.[166] This approach identified a number of protein vaccine candidates that are pathogen specific, antigenic, surface exposed, and expressed in vivo. Outer membrane iron receptors were discovered to meet multiple screening criteria, and recent intranasal vaccinations have been created and demonstrated to be protective against UPEC in mice.[167]

Clinical investigations have demonstrated the efficacy of acquired immunity as prophylaxis against recurrent UTIs in women and children. Both vaginal and intramuscular immunization with inactivated uropathogenic bacteria have resulted in significantly increased levels of sIgA.[168] In a small trial involving only 10 girls with recurrent UTIs and an equal number of healthy controls, intramuscular immunization also resulted in significantly fewer recurrences in the girls vaccinated.[169] Although these results are promising, the full value of such vaccines to prevent

pyelonephritis will be critically assessed only by appropriately controlled, large clinical trials.

Currently, there are no licensed UPEC vaccines available in the United States. Two formulations that are available outside the United States are Uro-Vaxom, which is a daily oral capsule containing membrane proteins from 18 *E. coli* strains, and SolcoUrovac, a vaginal suppository containing 10 heat-killed uropathogenic strains.[170,171]

Anatomical Host Defense Factors

By necessity, these host defense factors are closely interrelated to the pathogenesis of UTIs and are functional at specific sites in the urinary tract, beginning with the route of entry of bacteria.

Perineum

Considerable clinical and experimental evidence has clearly established an ascending or retrograde urethral route of entry of bacteria in the majority of UTIs. The same bacterial strains causing urinary infections can be found on perineal cultures prior to bladder invasion. This is in contrast to negative perineal cultures in healthy controls.[172–175] The usual organisms originate from fecal floras that colonize the perineum.[176] In contrast, hematogenous seeding of the urinary tract is an uncommon source of urinary infection in children. When this is the cause of a renal infection, a cortical abscess, rather than classic pyelonephritis, is more likely to occur.

An infant's initial exposure to uropathogenic bacteria occurs at the time of birth, subjecting infants born to bacilluric mothers to a fourfold greater risk of UTIs.[177,178] It has been postulated that other host defense factors mature during the first year of life, resulting in a decreased risk of both periurethral colonization and recurrent UTI. Overall, the quantities and species of colonizing bacteria in the periurethral area diminish during the first year of life until few remain at age 5 years.[172] Meanwhile, normal periurethral flora may even be protective against urinary infection by competitive interference with attachment of uropathogenic bacteria.[179,180] This potential protective effect can be altered by the administration of antimicrobial agents, given for any reason. In a study of children with first-time APN, significantly more children had been recently treated with antibiotics, usually for non-UTIs, than controls.[26] In general, the genitalia of infant boys are more heavily colonized than those of infant girls, and when colonized, infant boys carry *E. coli* more frequently than do girls. These data concur with Winberg's epidemiological findings that UTI occurs less frequently with advancing age, and that boys younger than 6 months are at greater risk than their female counterparts.[181]

Ultimately, an infant's own intestinal tract may become colonized by bacteria with uropathogenic potential. Wold et al. reported on 13 girls with ABU who underwent characterization of fecal flora. Resident strains isolated from affected girls who more commonly expressed P-fimbria were adherent to colonic epithelium in a mannose-resistant fashion, and were one of several uropathogenic serotypes present when compared with transient strains of *E. coli*.[182] Plos et al. confirmed these findings in a prospective review of fecal isolates from children with UTIs. Affected children demonstrated intestinal colonization with P-fimbriated *E. coli* more frequently than healthy controls both during infection (86% vs. 29%) and during infection-free intervals (40% vs. 29%).[183]

Since Bollgren and Winberg's original work in 1976 in school-aged girls with a history of recurrent UTIs, three additional studies have reported on the natural history of periurethral colonization.[61,172,184,185] Despite the widely accepted concept of an ascending route of infection, the mere presence of uropathogenic bacteria on the perineum did not portend symptomatic UTI. Schlager et al. studied the association between periurethral colonization and recurrent UTI in a cohort of seven toilet-trained girls (3–6 years of age).[61] Each girl underwent weekly periurethral and urinary cultures during a 6-month period immediately following her first UTI. Almost half (43%, 53/122) of the periurethral cultures were positive; however, a positive perineal culture was obtained equally as often in the absence of urinary infection as it was prior to a symptomatic recurrence. Moreover, in only one of the four recurrences was the causative organism isolated from a perineal culture. Similarly, although heavy periurethral colonization has been reported in 75%–80% of healthy infants and toddlers of both sexes, only 1%–3% become infected.[17] In a study similar to Schlager's, Brumfitt et al. found that perineal colonization by the responsible organism did not precede the symptomatic recurrent UTI in up to 34% of the adult women studied.[185] These data may reflect the transient nature of bacterial species colonizing the perineum. Alternatively, these findings may reflect the short time course between initiation of perineal colonization and symptomatic UTI by uropathogenic bacteria in certain individuals.

Although it is not unreasonable to suspect that an abrupt change in the expression of certain key virulence factors might precipitate ascent from the perineum to the bladder, some data exist to refute this hypothesis. Schlager et al. characterized the expression of six virulence factors among *E. coli* colonizing the bladder in the absence of symptoms and those causing symptomatic UTI in seven girls. Although P-fimbriae were commonly identified in infecting species of *E. coli*, none of the six virulence factors, including P-fimbria, accurately predicted which colonizing species would ultimately cause symptomatic infection.[61] Thus, although sufficient evidence exists to support bacterial ascent into the bladder from the perineum as the mode of entry, the facilitating events in that mechanism remain poorly understood.

Prepuce

Historically, a hematogenous route of infection, rather than ascent into the urinary tract from the perineum, has been suggested in the newborn. This proposal was based on the more frequent finding of bacteremia associated with UTI in this age group.[186] However, others have not substantiated a higher incidence of bacteremia in neonates compared with other infants and children with febrile UTIs.[18,63] Furthermore, the increased risk for UTI (including pyelonephritis) in uncircumcised boys compared with both girls and circumcised boys provides additional convincing

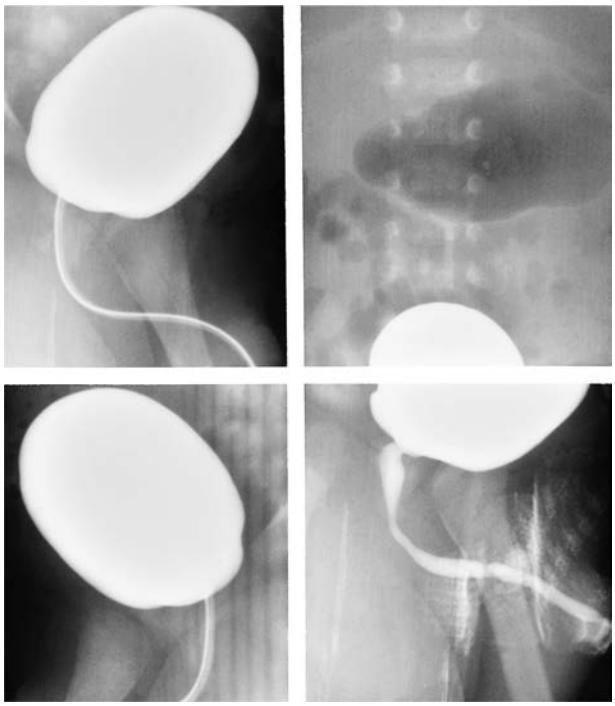

FIGURE 7.4 Voiding cystourethrogram demonstrating the absence of vesicoureteral reflux and obstructive pathology (posterior urethral valves, ureterocele) in an uncircumcised infant boy with acute pyelonephritis confirmed by ^{99m}Tc DMSA renal scan.

support for an ascending route of infection even during the first several months of life (Figure 7.4). In fact, more than 90% of boys with febrile UTIs during the first year of life are uncircumcised.[6,187] In 1985, Wiswell et al. initially found a 20-fold higher rate of UTI among infant boys who were not circumcised than among those who were (4.12% vs. 0.21%). Subsequently, two larger cohort studies by the same investigator, encompassing 637,097 infants, found the rate of UTI among uncircumcised boys to be less than that originally described, but still significantly greater (10-fold) than the incidence of UTI among those circumcised (Table 7.7).[188,189]

Evidence exists to implicate the prepuce as a reservoir for uropathogenic bacteria. Wijesina et al.[190] prospectively cultured the periurethral flora before and after circumcision in 25 boys. Prior to circumcision, 52% (13/25) of the boys were colonized by potentially uropathogenic organisms, as opposed to none of the boys after circumcision. Other studies have demonstrated that uropathogenic P-fimbriated *E. coli* adhere well to the mucosal surface of the prepuce, whereas nonpathogenic *E. coli* do not.[39,187,189]

TABLE 7.7 Incidence of UTI in female and circumcised and uncircumcised male infants (0–1 years old) born in U.S. army hospitals (1974–1983)

	Total no.	No. with UTI	Rate per 1000
All males	217,116	661	3.0
Circumcised	175,317	193	1.1
Uncircumcised	41,799	468	11.2
Females	205,212	1164	5.7

One must wonder what differs in neonatal boys, recognizing that the incidence of pyelonephritis declines throughout childhood despite the persistence of foreskin and periurethral colonization. In a retrospective study, Kim suggested that the increased risk of UTI in neonates might be related to the inability to retract the foreskin.[191] However, many boys cannot retract their prepuces until adolescence. Despite this conflicting evidence, the periurethral area of the uncircumcised infant is a closed space harboring bacteria with the potential to cause serious urinary infection in some boys.[39,192] Consequently, circumcision may help to prevent UTI in male infants by removal of the mucosal surface necessary for bacterial adherence to occur. However, since even in uncircumcised boys the incidence of UTI is low, the debate regarding routine circumcision as a preventive health measure will likely continue. Justification for circumcision in boys who have other risk factors for UTI, such as antenatal detected hydronephrosis associated with posterior urethral valves, megaureters, or high-grade VUR, is more easily argued.

Urethra

The short urethra in girls appears to be the most obvious explanation for the increased relative incidence of UTIs in girls compared with in boys after the first 6–12 months of life. Narrowed urethral caliber, historically blamed as the preeminent factor influencing susceptibility to lower UTIs in girls, does not play a role. It has long been established that the intrinsic urethral luminal size is not significantly narrower in those girls who are bacteriuric compared with those who never have been infected.[193,194] In fact, both of these studies demonstrated that the urethral diameter was slightly larger in infected groups than in those never infected. Consequently, there is no role for urethral dilatation or other cystoscopic procedures in the routine management of childhood UTIs.

Other commonly held misconceptions related to the etiology of UTIs are that improper wiping techniques and bubble baths predispose to urinary infections. However, there is no reported evidence to support these myths. The strongest evidence against improper wiping techniques being a cause of UTIs is that more than 95% of non-toilet-trained infants never develop urinary infection despite daily exposure to soiled diapers. Although bubble baths may occasionally cause dysuria from local meatal or vaginal irritation, there is no association with bacterial cystitis. More important for urethral ascent into the bladder is the ability of uropathogenic bacteria to attach to uroepithelial cells. Similar to the findings with periurethral cells, increased adherence of bacteria to uroepithelial cells has been demonstrated in children prone to urinary infections.[95,195,196] This implies a difference in host receptor density or affinity that influences an individual's susceptibility to infection.

Bladder

Vesicoureteral Reflux

Numerous reports have documented that VUR is present in 25%–50% (average 35%) of children with culture-documented UTIs.[197] In contrast, in a survey of the literature, Bailey reported an incidence of VUR in children without UTI of only 0.4%–1.8%.[198] Similar findings were reported by Ransley, who compiled voiding cystograms in 535 children without a history of UTI and found VUR in only 7 children (1.3%).[199] VUR, when present, continues to be the most significant host risk factor in the etiology of childhood pyelonephritis. The risk for both APN and subsequent renal scarring is directly related to the severity of VUR. In one prospective study of children with febrile UTIs, approximately 80% of patients with VUR demonstrated changes consistent with APN on technetium-99m (Tc-99m) DMSA renal scans, including 100% of patients with moderate to severe reflux (grades III–V/V).[63] In contrast, only 60% of patients without demonstrable reflux had evidence of APN on the DMSA scan. Kidneys associated with moderate or severe reflux were twice as likely to demonstrate abnormalities on DMSA scans (67%) when compared with kidneys with mild (32%) or no (34%) reflux. In a compilation of 10 published clinical studies of children with febrile UTIs, DMSA renal scan abnormalities have been reported in 50%–80% of children.[200] When VUR was present, approximately 80%–90% of patients had abnormal studies, including almost all with moderate or severe VUR.

The presence of VUR appears to compensate for decreased virulence of *E. coli* in patients with recurrent pyelonephritis.[49] When there is reflux of infected urine from the bladder into the upper urinary tract, bacteria do not require special virulence properties, such as cellular attaching ability, to ascend from the bladder to the kidney. In one study of girls with recurrent pyelonephritis, infections were caused by P-fimbriated *E. coli* in only 36% of those with VUR compared with 71% of those without VUR.[64] Despite the important role that VUR plays when it is present, studies of children with febrile UTIs have reported that the majority of patients (60%–68%) with abnormal DMSA renal scans demonstrating acute pyelonephritic changes do not have demonstrable VUR at the time of investigation (Figure 7.5).[200]

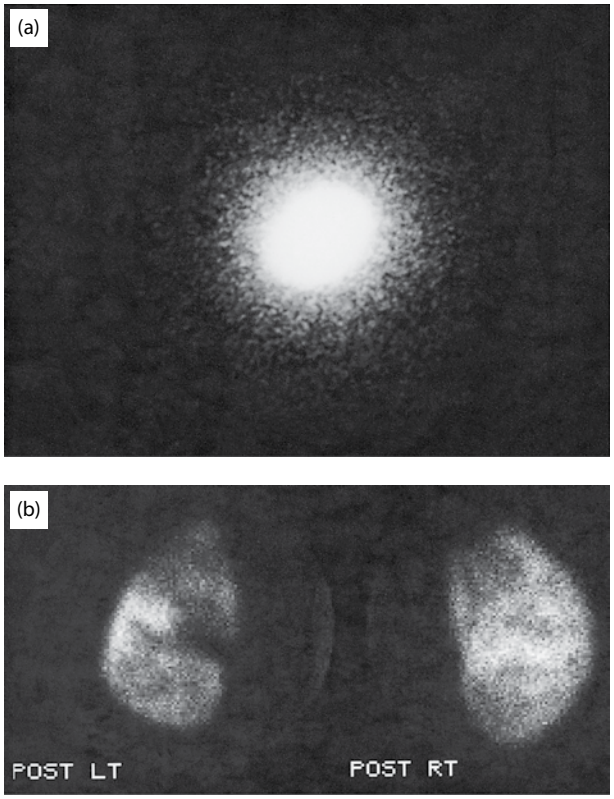

FIGURE 7.5 (a) Isocystogram demonstrating the absence of vesicoureteral reflux in a child with (b) ^{99m}Tc DMSA renal scan documented acute pyelonephritis (upper and lower poles are affected).

Dysfunctional Elimination

Abnormal voiding dynamics or bowel or bladder dysfunction is an important host risk factor for recurrent UTI, persistent VUR, failed interventional therapy, and acquired renal scarring.[201] Common voiding disorders in children prone to UTI range from the small-capacity, unstable bladder characterized by frequency, urgency, posturing, and wetting, to the infrequent voider ("lazy bladder syndrome") characterized by very infrequent voiding, a large-capacity bladder, paradoxical incontinence (wet despite a large bladder capacity), and constipation. The prevalence of some of these is listed in Table 7.7. Numerous reports have linked dysfunctional voiding and recurrent UTIs in children.[202–208] Attention has also been focused on the association between dysfunctional voiding and the presence of VUR in infants and children with recurrent UTIs.[206,209] The predisposition to recurrent UTIs and VUR in children with dysfunctional voiding is related to the presence of residual volume resulting from inadequate emptying of the bladder, increased intravesical pressure created by uninhibited bladder contractions, and bladder overdistension from infrequent voiding habits.[210] The elimination of bacteria from the bladder by frequent and complete emptying plays a significant role in preventing infection.[211] In a group of girls followed with ABU, the incidence of recurrent bacteriuria correlated directly with bladder emptying. Average residual volumes in those with ABU were 23.7 mL, whereas the mean residual volume in normal controls was 1.1 mL. On follow-up, recurrent bacteriuria was present in 75% of those with more than 5 mL of residual urine, compared with only 17% of those with less than 5 mL of residual urine.[15] The establishment of normal voiding habits in these children has been shown to reduce the incidence of recurrent UTIs.[212–214]

Initial evaluation should include obtaining a detailed history regarding urinary frequency, urgency, prolonged voiding intervals, daytime wetting, perineal or penile pain, holding maneuvers, and constipation or encopresis.[200] Squatting, delayed or infrequent micturition, urgency, constipation, and/or encopresis are significant symptoms that frequently can be elicited in 50%–94% of children with UTI.[205–207,215–219] Hellström et al. reported an abnormal voiding history in up to 49% of girls presenting between 3 and 5 years of age with their first UTI. Specifically, the presence of daytime urinary symptoms

strongly correlated with the risk for subsequent infection.[18] In a related study of the same children, Hansson found that a majority of girls with "covert" bacteriuria had urodynamic evidence of dysfunctional bladders when compared with controls.[203] Wan et al. evaluated the relationship between toileting habits and anatomic abnormalities that predispose to infection in 101 children with UTI (77 girls and 24 boys). Ninety percent of the children without structural abnormalities demonstrated dysfunctional elimination as a contributing factor to their urinary infections, compared with 40% of those patients found to have a structural abnormality, such as VUR.[220]

Similarly, there is a definite correlation between constipation and urinary incontinence, VUR, and recurrent UTIs in children.[221,222] Constipation is classically characterized by infrequent bowel movements that are large caliber and firm. This may be associated with perineal and/or abdominal pain from colonic distension. Paradoxically, children with constipation may be referred for encopresis (fecal soiling), a manifestation of the elimination of loose stool around feces impacted within the rectal vault. Unfortunately, physical examination of the constipated child is unreliable, and often a soft abdomen or empty rectal vault is encountered even when significant constipation is present radiographically. Likewise, the diagnosis of constipation can be difficult in children under 5 years who are unable to provide an accurate history.

A growing body of evidence suggests that constipation is an important facet of disordered elimination that, if appropriately managed, can help reduce the number of recurrent UTIs and promote resolution of VUR. Although this theoretically may be the result of mechanical factors related to compression of the bladder and bladder neck by a hard mass of stool, it is more likely due to the frequent coexistence of constipation with dysfunctional voiding and incomplete bladder emptying. In an epidemiological questionnaire surveying 1557 Danish children 7–8 years old (863 girls, 728 boys, 6 gender unknown), the overall prevalence of encopresis was 13.9% (5.6% girls, 8.3% boys) (Table 7.8).[223] Among the girl respondents, 75 had a history of UTI, and 13% of these suffered from encopresis versus only 6% of the girls without UTIs. Moreover, in a prospective study of 234 chronically constipated children, approximately one-third of the children demonstrated associated daytime incontinence (24%) and nighttime incontinence (34%), which reflects the degree to which bowel and bladder elimination disorders are interrelated.[213] The resolution of constipation resulted in disappearance of daytime and nighttime incontinence in a majority of children (89% and 63%, respectively). Most significant was the impact on the frequency of UTIs (approximately 10% of the total), which completely disappeared in children without structural abnormalities.

Chronic constipation also plays a role in the etiology of recurrent UTIs in children with primary VUR. Recently, Koff et al.[224] has demonstrated that up to 50% of the children with VUR who might otherwise be considered "normal" have significant disorders of elimination (Table 7.9). In children with dysfunctional voiding, the presence of residual urine and elevated voiding pressures during UTI is more likely to result in significant postpyelonephritic renal scarring than anticipated for the grade of VUR present. The risk of febrile UTI in children with VUR on prophylactic antibiotics is greater in those with bowel and bladder dysfunction 44% versus those without 13%.[201] Perhaps because of more frequent breakthrough infections while on antibacterial prophylaxis, these children have been found to be at increased risk for progressive renal scarring.[225]

Of the dysfunctional elimination symptoms, chronic constipation was the most prevalent in the presence of recurrent UTIs.[224] Many without a history of UTI had detrusor instability in the absence of infection. Among those with VUR, dysfunctional elimination significantly increased the risk of breakthrough UTIs, resulting in more frequent reimplantation surgery in these children. Endoscopic therapy results in a smaller success rate among children with bowel or bladder dysfunction than among those without dysfunctional elimination, while no such difference in success rate is seen following open surgery.[201] Additionally, the rate of postoperative UTI is 21% versus 5% for those with and without bowel or bladder dysfunction.

The rate of reflux resolution 24 months after diagnosis is less for children with bowel or bladder dysfunction than for those without (31% vs. 61%, respectively).[201] It was demonstrated that it took 1.5 years longer for primary VUR to resolve in children with dysfunctional elimination (constipation included) than in those without any elimination symptoms, despite a lower mean grade of reflux in those with dysfunctional elimination. One study by Herz et al. showed that children with APN have a higher incidence of dysfunctional elimination that is clinically more refractory to treatment, and that when dysfunctional elimination is treated effectively, the increased susceptibility to renal scarring is decreased.[226]

TABLE 7.8 Prevalence of symptoms characteristic of dysfunctional elimination in 7- to 8-year-old school children: results of Danish epidemiological questionnaire survey

	Girls (%)	Boys (%)
Urge symptoms	20	21
Day wetting	13	9
Night wetting	13	22
Nocturia	7	6
Encopresis	5	8
Emptying difficulties	8	7

Although treatment for bowel or bladder dysfunction has a distinct benefit for patients, there are no standardized treatment programs for dysfunctional elimination. The current standard of care includes common elements, such as timed voiding, relaxation measures, biofeedback if available, anticholinergic medications, and treatment for constipation.[227]

Upper Urinary Tract

Obstruction and Hydronephrosis

Urinary obstruction and/or hydronephrosis may occur at the ureteropelvic junction, the ureterovesical junction, or the posterior urethra in boys with valves. Patients with obstruction may present with severe infection. Ectopic ureters, with or without associated ureteroceles, also represent obstructed pathology. However, such anomalies are present in only a minority of children with UTIs. In fact, recent prospective studies of children presenting with first-time febrile UTIs have reported significant obstructive uropathy in less than 1%.[228] Perhaps this lower incidence is due in part to the increased detection of hydronephrosis on prenatal ultrasonography prior to the development of clinical infection. The increased predisposition to infection presumably results from impairment of urinary flow, with resultant stasis that compromises bladder and renal defense mechanisms. Both obstruction and high-grade reflux result in an increase in the residual volume of urine in the bladder or dilated urinary tract, permitting the multiplication of bacteria in the urine.[211] Obstruction also inhibits the mechanical washout or flushing effect associated with ureteral peristalsis and effective micturition, and may alter other local defense factors as well. All these factors result in increased susceptibility of the parenchyma to infection and damage.

DIAGNOSIS OF URINARY TRACT INFECTION

UTIs can be reliably diagnosed only by urine culture. Symptoms of dysuria, urgency, frequency, and enuresis are nonspecific and may be the result of vulvitis, urethritis, dysfunctional voiding, or nonspecific causes, such as dehydration associated with febrile illness. In 34 children with lower urinary symptoms alone, urine culture demonstrated significant bacteriuria in only 18%; 40% of those with sterile urine had upper respiratory tract infection.[229] Similarly, Heale et al. found that of 378 children with specific urinary complaints, only 14.3% had urinary infection. Thirty-three percent with flank pain, frequency, and/or dysuria and 31.5% with the recent onset of wetting had UTI, whereas only 4.2% with chronic nocturnal enuresis were infected.[230]

Urinalysis

Although routine urinalysis can be helpful in calling attention to those who might be infected, the association of inflammatory cells in the urine by itself is at best only about 70% reliable.[6,231,232] The finding of significant pyuria on routine urinalysis varies with the volume of urine centrifuged and examined, the force and duration of centrifugation, the volume in which cells are resuspended, and observer error.[233] Urine microscopy for bacteria significantly improves the reliability of urinalysis for the detection of urinary infection, particularly when one combines this with examination of urinary sediment for pyuria.[234] Jenkins et al.[235] reviewed approximately 40 publications reporting urine microscopy for bacteria and found a wide variation in methodology and diagnostic criteria. They concluded that the least reliable method was examination of unstained, uncentrifuged urine. When stained, centrifuged urine was examined, the sensitivity using the criteria of one or more organisms per oil immersion field was greater than 95% when compared with urine culture growing $\geq 10^5$ colony-forming units (CFU)/mL. The specificity was at least 95% when more than five organisms per oil immersion field were viewed. Hoberman et al. have recently compared quantitative urine cultures with an "enhanced" urinalysis for the detection of pyuria and bacteriuria in urine specimens obtained by catheterization in children presenting with fever. The data obtained demonstrated that UTI is best defined by more than 10 leukocytes/mm^3 on urinalysis combined with urine cultures yielding more than 50,000 CFU/mL.[236] In contrast, dipstick determination for the presence of leukocyte esterase and nitrite yielded sensitivities of only 52.9% and 31.4%, respectively, in detecting clinically significant bacteriuria (greater than 50,000 CFU/mL). In both this and another study of febrile infants, the findings of urinalysis were compared with the results of Tc-99m DMSA renal scans. Both studies concluded that APN in febrile infants is almost always associated with the finding of pyuria on urinalysis.[236,237]

Partly as a result of the technique and operator-dependent variability with urine microscopy, a number of enzymatic methods for the detection of bacteriuria or pyuria have been developed. The two most popular are the leukocyte esterase and nitrite reductase tests. These studies are inexpensive, rapid, and easy to perform.

Leukocyte Esterase Test

The leukocyte esterase dipstick test demonstrates the presence of pyuria by histochemical methods that specifically detect esterases in the neutrophils. When compared with chamber count methods, studies have reported sensitivity as high as 88%–95% for the detection of pyuria using a cutoff of 10 or more leukocytes/mm^2.[21,41,238] However, in a study that evaluated 110 children with fever and positive urine cultures, the leukocyte esterase test had sensitivities of only 52.9% and 66.7% in detecting ≥ 10 and ≥ 20 leukocytes/mm^3, respectively.[231] Furthermore, one would not anticipate this test to be any more sensitive than the finding of pyuria alone for the identification of children with positive urine cultures.

Nitrite Test

Bacteria convert urine nitrate to nitrite. The nitrite method employs reagent paper impregnated with sulfanilic acid and α-naphthylamine that form a red azo dye when in contact with nitrite. Thus, a positive colorimetric assay implies the

presence of bacteria in the bladder. However, a relatively long incubation period (4 hours) is required for conversion of nitrate to nitrite. For this reason, first morning urine sample in a toilet-trained child is the best specimen to test. A single test on a randomly collected urine specimen was reported to have a sensitivity of only 29.2%–44% on 790 urine specimens using dipsticks from two manufacturers. However, the specificity was 98% when the test was positive.[237,239] This test is not a reliable office screening method when used alone.[238]

Combining the leukocyte test and the nitrate test on a single dipstick has improved the accuracy to detect or exclude UTI. In a review of rapid methods to detect UTIs, Pezzlo reported a sensitivity of 78%–92% and a specificity of 60%–98% when using the combination test.[240] In the absence of positive Leukocyte esterase (LE) and nitrite, the diagnosis of UTI and ABU is unlikely.[241] However, the accuracy is affected by the probability of the patient being infected based on clinical findings.[240,242] Accordingly, urine culture may be omitted when the dipstick test is negative only when there is limited suspicion for UTI based on clinical symptoms. Conversely, urine culture should be obtained in any patient suspected of having a UTI or in whom the dipstick test is positive.

Urine Culture

In the pre-toilet-trained group, the urine specimen is often obtained by applying a collection bag. The results are reliable only when the specimen is negative. Contamination is directly related to the length of time the bag is in place. If a specimen has not been obtained within 30 minutes of application, reliability begins to decrease. Removing the appliance and plating or refrigerating the urine immediately after the child voids is paramount. Having the parent apply the bag before leaving for the physician's office in an effort to shorten the wait is acceptable only when the cultured specimen is negative. When confirmation of voided urine or immediate treatment is necessary, bladder catheterization or SPA should be employed. A feeding tube (8–10 French) inserted only a few centimeters into the bladder is ideal for catheterization. In girls and boys who can void on command, midstream specimens are more reliable than bag-collected specimens.

Young children are particularly favorable candidates for SPA because of the abdominal location of their urinary bladders. However, the procedure cannot be expected to be successful when the bladder is empty. This is the major drawback of SPA. If urine is not obtained initially, time should not be wasted in a sick child who requires antibiotic treatment. Urethral catheterization should be done. SPA is performed after first cleaning the suprapubic area with an antiseptic solution. A 21- to 25-gauge needle is inserted perpendicular to the patient in the midline one finger breadth above the symphysis. Although a local anesthetic can first be infiltrated, this appears unnecessary and may actually cause more pain than a quick in-and-out aspiration. It is practical to apply a U-bag to the perineum prior to cleansing the abdomen. Many times, the child voids during preparation for aspiration, obviating the necessity for the procedure if the voided urine is immediately plated or refrigerated.

It has often been stated that "any number of bacteria" obtained by SPA is significant. Since the bladder is a reservoir and this method of collection depicts the number of bacteria in that reservoir, one should not anticipate colony counts significantly different from those properly collected by other means. Ginsburg and McCracken found ≥100,000 CFU/mL in 96% and 40,000–80,000 in the remaining 4% of 100 febrile infants with bacteriuria demonstrated on SPA.[6] None showed fewer than 40,000 colonies. Nelson and Peters had previously reported similar results in a study of premature and term infants.[243] Hoberman et al. recently reported the results of positive urine cultures on specimens obtained by catheterization in 110 febrile infants of <2 years old.[236] Of 110 urine cultures with ≥10,000 CFU/mL, 92 (84%) had ≥100,000 CFU/mL, 10 (9%) had 50,000–99,000 CFU/mL, and only 8 (7%) had 10,000–49,000 CFU/mL. Furthermore, urine specimens with 10,000–49,000 were much more likely to yield gram-positive or mixed organisms than specimens with >50,000 CFU/mL. These authors concluded that UTI is best defined by ≥10 leukocytes/mm^3 and colony counts of ≥50,000 on catheterized specimens. Thus, colony counts from the bladder of <50,000 CFU/mL are suspect regardless of the manner in which the urine was collected.

Fevers

Traditionally, fevers of >101.5°F have been used to help define APN clinically. Studies by Biggi et al. have demonstrated that high fever is not a reliable sign to discriminate pyelonephritis documented on a DMSA scan from a lower UTI.[244] They showed that the sensitivity and specificity of a temperature greater than 39.1°C to diagnose pyelonephritis were 64% and 38%, respectively. This was supported by a small pilot study by Farnsworth et al. that demonstrated that 41% of individuals who had parenchymal involvement seen on DMSA scan were afebrile.[245]

Biomarkers

Biomarkers are defined as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[246] Effective biomarkers can be used to monitor disease burden, predict therapeutic response, and measure adverse effects. Diagnostic biomarkers may be one of the most difficult to develop because rigorous negative and/or positive predictive values are needed for the biomarker to be clinically applicable and not just statistically significant.[247] Unfortunately, variation in study designs and lack of appropriate prospective clinical studies have made it difficult to define clinically applicable markers for VUR and APN.

There have been many attempts to identify biomarkers for APN and/or renal scarring that have not proved to be clinically significant.

Angiotensin-converting enzyme genotype: Hohenfellner et al. reported that patients with the angiotensin-converting enzyme (ACE) DD genotype were at higher risk for renal parenchymal damage and glomerular filtration rate (GFR) reduction secondary to obstruction or VUR than those with

the II or DI genotype.[248] These data were disputed by others who demonstrated no difference in renal scarring regardless of VUR for any genotype.[249]

N-acetyl-β-glucosaminidase and β-2-microglobulin: Others have evaluated the role of urinary N-acetyl-β-glucosaminidase (NAG) (a renal tubular enzyme thought to be a marker of tubular damage) and β-2-microglobulin (β_2M) (a low-molecular-weight circulating protein with increased fractional excretion in children with tubulointerstitial disease) in the diagnosis of pyelonephritis in febrile children. Unfortunately, elevation of this urinary marker has been found in both children with febrile UTIs and children with sterile urine who had severe renal scarring associated with high-grade VUR, making these markers unreliable for the diagnosis of APN.[104,250,251]

Procalcitonin: Procalcitonin (PCT), on the other hand, has been studied in depth and is emerging as an effective biomarker to differentiate lower UTI from pyelonephritis in the pediatric age group. First described by Assicot et al. as a marker of bacterial invasion, PCT is produced in C cells of the thyroid gland in healthy humans with upregulation during a severe bacterial infection. It is also produced by the monocyte–macrophage system locally at the site of inflammation.[252] Gervaix et al. demonstrated a higher level of PCT in the setting of renal parenchymal damage on DMSA scans than in patients who had lower UTI.[253] Pecile et al. prospectively showed that mean PCT increased proportionally with the extent of renal involvement on DMSA scan, and that PCT levels at admission were lower in patients with completely reversible lesions versus those with partially reversible lesions or renal scarring.[254] Benador et al. confirmed these findings in a prospective study of 80 children evaluating PCT, C-reactive protein (CRP), and white blood cell (WBC) count in pyelonephritis and lower UTI. They demonstrated statistically significant differences between the two groups for all three parameters; however, only PCT had good correlation with increasing severity of scintigraphic changes noted on DMSA (PCT of 5.37 μg/L in pyelonephritis group vs. 0.38 in the lower UTI group).[255] Similarly, Gürgöze et al. conducted a prospective study of 76 children with UTI using a PCT cutoff of 0.5 μg/mL to diagnose pyelonephritis demonstrated by DMSA scan. In this study, the sensitivity and specificity for detection of acute pyelonephritic changes on DMSA scans were 94% and 58%, respectively.[256] Using the same cutoff value for PCT, a similar study found a sensitivity of 94.1% and specificity of 89.7% for the detection of APN.[257] Sheu et al. recently reported a prospective study of 112 children less than 2 years of age with their first known febrile UTI. All were evaluated with PCT, CRP, and serum WBC counts at presentation before antibiotics were started. All had a DMSA scan within 5 days of admission and again at 6 months. Using a cutoff value of 1.0 μg/mL, they reported a sensitivity of 82% and specificity of 92% for DMSA-proven APN. They also found that a cutoff value of 3.5 μg/mL had an 18 times increased risk for the development of subsequent renal scarring.[258]

In addition to pyelonephritis versus lower UTI, PCT had been investigated as a biomarker for prediction of high-grade VUR. Leroy et al. reviewed 12 studies representing 526 patients where a PCT-preferred threshold of 0.5 ng/mL was associated with VUR grade III or greater as a continuous and binary variable with a sensitivity of 83% and specificity of 43%.[259] This idea is supported in a study that determines PCT to be a good predictor of VUR in children with first febrile UTI; however, other studies dispute these claims.[255,260]

Interleukins: IL-8 had been shown to be increased during acute UTI and may help identify children with VUR.[261] Jantausch et al. conducted a prospective study on children age 0–12 years with positive urine cultures versus controlled matched febrile subjects with infections other than UTI. At the time of admission, the median urinary IL-6 concentration for subjects with proven bacterial UTI was 397 pg/mL versus 0 pg/mL for the controls. The median IL-8 concentration for the bacterial UTI group was 5809 pg/mL versus 0 pg/mL for the controls.[262] Additional studies suggest that gene polymorphisms of IL-8 may play a role in identifying children who are susceptible to pyelonephritis with or without VUR.[263] IL-6 and IL-8 have been studied to differentiate between pyelonephritis and lower UTI. Sheu et al. investigated the role of IL-6 and IL-8 in diagnosing APN.[264] APN was confirmed with DMSA scan in 78 children with first febrile UTI. The initial values of both interleukins, IL-6 and IL-8, in serum and urine were significantly higher in patients with APN than in those with lower UTI and healthy controls. IL-6 in serum and urine significantly correlated with each other and with the presence of fever, elevated CRP, and leukocytes in the urine. Serum IL-8 and urinary IL-8 significantly correlated with each other but not with clinical symptoms.[264] However, ongoing research is needed to confirm the clinical application of these results since others, such as Krzemień et al., have showed no difference in urinary IL-6 and IL-8 in subjects with APN and those with lower UTI.[265]

WBC: WBC counts of >14,601 cells/mm^3 have a sensitivity and specificity of 56% and 58% to diagnose pyelonephritis.[244]

CRP: The CRP is 64% sensitive and 68% specific for diagnosis of pyelonephritis.[247]

ESR: The sensitivity of the erythrocyte sedimentation rate (ESR) to determine renal parenchymal damage varies with the cutoff. Garin et al. performed a retrospective study using a cutoff of >10 mm/h for ESR that yielded a sensitivity and specificity of 100% and 8%, respectively.[266] However, in a prospective study using a cutoff of >68 mm/h for ESR, Biggi et al. reported a sensitivity and specificity of 48% and 50%, respectively.[244]

At the present time, additional prospective studies are needed to confirm the accuracy of candidate biomarkers for the detection of APN and/or subsequent renal scarring. If these prove to be reliable, evaluation with biomarkers at the time of presentation with UTI could be used to direct a more selective approach to imaging of children.

Proteomics

Proteomics is a rapid screening tool used for identifying new targets of interest and characterizing the protein content within cells, tissues, body fluids, and whole organisms at a particular stage or condition. Its goal is to analyze all proteins in a particular sample and determine splices and modifications to search for biological and clinical

relevance.[247] Increased understanding of the changing proteome during disease has the potential to identify many new biomarkers of disease and new therapeutic targets of disease. To date, potential biomarkers have been discovered using urine proteomics that are clinicaly applied in renal transplant, allograft nephropathy, focal segmental glomerosclerosis, renal and bladder cancer, and others.[267–275] Lee et al. have demonstrated a potential set of markers related to normal nephrogenesis and developmental maturation in rodent kidneys.[276] These studies suggest that there is significant potential for proteomics to facilitate the discovery of future biomarkers.

CLINICAL PRESENTATION AND LOCALIZATION

As one would anticipate, the classic signs and symptoms for UTI are usually lacking in the very young. Instead, nonspecific symptoms, such as irritability, poor feeding, failure to gain weight, vomiting, and diarrhea, may be the only signs suggestive of an underlying problem (Table 7.9). In one study of children with symptomatic urinary infections, only 9% of 78 infants were initially referred with a suspected diagnosis of UTI.[277] Often absent in neonates, fever is present in most infants between 1 and 12 months old who present with symptomatic UTIs.[5,17,19] In fact, UTIs have been described as one of the most common serious bacterial illnesses among febrile infants and young children, with a reported prevalence ranging from 4.1% to 7.5%.[236] In one study of 945 infants who presented to a pediatric emergency room with fever, the overall prevalence of UTI was 5.3%.[278] The prevalence was highest in Caucasian girls, 17% of whom had a positive urine culture. In contrast, the prevalence of UTI among African American girls was only 3.5% and among boys it was 2.5%. Another prospective study reported UTI in 7.5% of 442 infants (less than 8 weeks of age) presenting to the emergency room with a fever of ≥100.6°F (38.1°C), only half of whom had abnormal urinalyses suggestive of UTI (>5 WBCs per high-power field or any bacteria present).[279] Thus, a urine specimen for culture, preferably collected by catheterization, should be obtained routinely whenever a nonverbal, non-toilet-trained child presents with unexplained fever.

As the child becomes verbal and is toilet trained, urinary tract symptomatology is more easily detected. Fever continues to be relatively common in toddlers with first-time symptomatic infection. However, fever is not as frequently associated with recurrent and/or long-standing infection. In older children, urgency, frequency, enuresis, and dysuria are common presenting symptoms. Failure to become toilet trained at the proper age may occasionally herald underlying chronic lower urinary infection. Although urinary tract symptoms such as vaginal pain, urinary frequency, dysuria, and enuresis are common following childhood sexual abuse, actual urinary infection is not.[280]

There are few population-based studies of symptomatic UTIs in childhood. The classic epidemiologic study by Winberg et al. was carried out between 1960 and 1966 in Goteborg, Sweden.[17] Subsequently, the special organizational structure of that city's pediatric medical care has afforded unique opportunities to perform ongoing epidemiologic studies of UTIs in children. Jodal reported a follow-up prospective epidemiologic study conducted in Goteborg from 1970 to 1979.[5] There were 952 females and 225 males (4.2:1) below the age of 10 years of age who were treated for a first-time symptomatic urinary infection (Figure 7.6). Of the 225 boys, 59% presented during the first year of life. The number of boys diagnosed in the higher age groups was low, especially over age 5. The number of first infections in girls was also highest in the first year of life (19%). A gradual decrease in number of girls with first-time infections was associated with increasing age. In both girls and boys, febrile infections, presumed to be pyelonephritis, predominated during the first year of life. Acute cystitis was most commonly seen between 2 and 5 years of age in

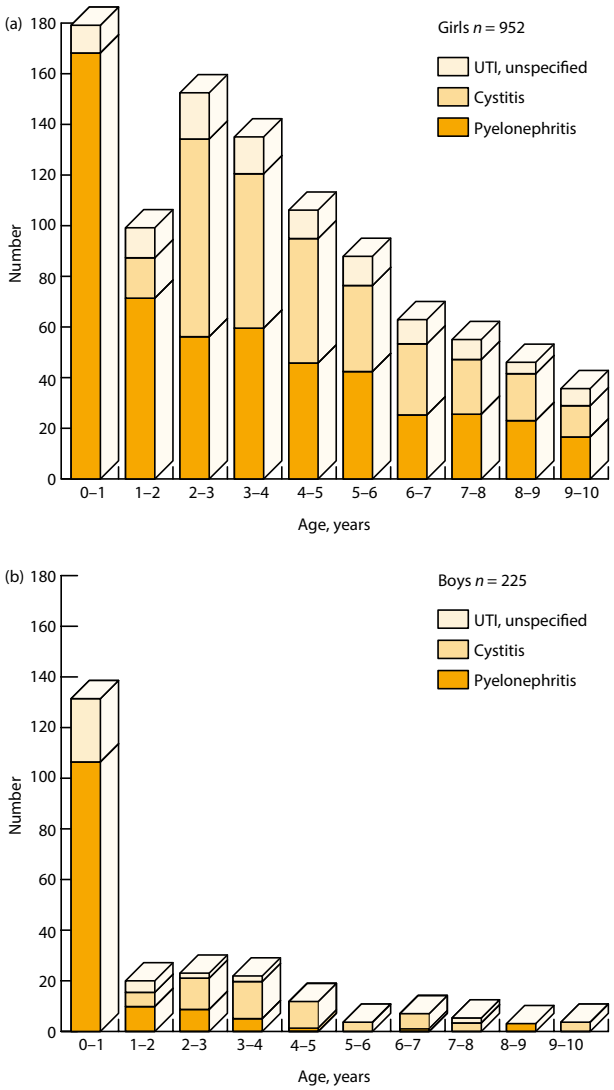

FIGURE 7.6 Children with first-time diagnosis of urinary tract infection at the Children's Hospital in Goteborg, Sweden, according to age and clinical diagnosis. (Reprinted from Jodal U. Urinary tract infection in children. In: Holliday M, Barratt TM, Avner Ed, eds. *Pediatric Nephrology*, 3rd edn. Baltimore, MD: Williams and Wilkins, 1994. With permission.)

both sexes, with a marked peak frequency in girls during the third year of life. As expected, infections during infancy were the most difficult to characterize as pyelonephritis or cystitis.

Asymptomatic Bacteriuria

The natural history and uroradiographic findings in patients with asymptomatic or covert bacteriuria vary according to the age of the patient and prior episodes of symptomatic infections. Screening bacteriuria does not necessarily represent ABU, as approximately one-third of school-aged girls with screening bacteriuria have a prior history of symptoms related to the urinary tract, and some have had previous symptomatic UTIs. It is unclear whether the prognosis is any different for children who have primary ABU compared with those in whom ABU develops following treatment of a symptomatic infection.

A study of asymptomatic and symptomatic bacteriuria in infants under 1 year of age reveals interesting differences in the two populations.[5] In 2 of 50 patients with ABU, clinical APN developed within 2 weeks of detection. The others remained free of symptoms. Mild reflux (grades I and II) was found in only five (11%). Of 45 left untreated, 36 spontaneously cleared the bacteriuria and 8 others became abacteriuric following antibiotic treatment for other reasons. Although asymptomatic recurrences developed in six (12%), no pyelonephritic recurrences occurred in this group during follow-up of at least 1 year. Follow-up urography, done in 36 patients, did not reveal any evidence of renal scarring. In contrast, among 40 infants with symptomatic infections, 1 patient had a significant ureteropelvic junction obstruction and 14 of 39 (36%) had VUR, including three with grade III or greater. Fourteen of 40 (35%) experienced recurrences, including 6 with APN and 3 with cystitis, whereas ABU was noted in 5. It was concluded that infants with ABU represent a low-risk group, with a tendency to spontaneously become abacteriuric, usually within a few months.

Considerable variation in uroradiographic findings has been reported in school-aged children found to have bacteriuria on screening. These studies have reported VUR in 19%–35% and renal scarring in 10%–26% children.[11,15,281–284] However, many of these children had a prior history of symptomatic UTIs, and others undoubtedly had infections during infancy that were overlooked or misdiagnosed. Although recurrent infections following treatment occur in up to 80%, the risk for development of APN in a girl older than 4 years of age with untreated ABU is small and seems to be associated with a change in bacterial strain, perhaps as a result of antibiotic treatment.[11,285] Follow-up by the Cardiff-Oxford Bacteriuria Study Group revealed that those school children who presented initially with a radiographically normal urinary tract remained normal in spite of persistent ABU.[286] Only in those children who had previous renal scarring did new scars or progression of scarring develop, and all these children had VUR. Other studies have shown that ABU is associated with low-virulence bacterial strains lacking the ability to adhere and cause symptoms.[51,129,287] Furthermore, there is considerable evidence that these organisms may be commensal with the host and may even protect against infection by more virulent strains.[288]

Cystitis

Acute cystitis in children is rarely associated with significant long-term morbidity. Typical symptoms that accompany acute cystitis in toilet-trained children include dysuria, frequency, urgency, and/or secondary-onset enuresis. Fever and systemic complaints are generally not a feature of the clinical picture. As previously mentioned, however, these same irritative lower tract symptoms are often seen in the absence of bacterial cystitis, mandating that a specimen for urine culture be obtained prior to institution of therapy.

Although the recurrence rate of lower UTIs is high, most cases can be considered little more than a nuisance, and recurrences tend to decrease or disappear by adolescence. However, it is worth noting that many children prone to recurrent lower UTIs have voiding dysfunction, particularly infrequent voiding. Typically, these children do not void for 1 or 2 hours after awakening in the morning, and then may void only two or three times throughout the day. Consequently, bladder capacity is abnormally large and bladder emptying is often incomplete. Often, these children also have chronic constipation, including encopresis in some. Other children with recurrent cystitis have underlying bladder instability associated with urinary frequency, urgency, and urge incontinence and posturing associated with a reduced functional bladder capacity. Girls with a history of UTI are significantly more likely to report a variety of chronic voiding disturbances than girls without a history of UTI (Table 7.10).[18,223] In some cases, recurrent UTIs may be a precipitating factor to the child's voiding disturbance. Conversely, primary bladder instability and/or infrequent voiding may itself contribute to an increased susceptibility to UTIs. In contrast to daytime voiding disorders, isolated bedwetting is rarely associated with a history of previous UTI.[18]

Approximately 10% of susceptible girls will have a recurrent infection shortly after completion of a course of antibiotic therapy. These children have chronic symptoms of bladder instability. Squatting or posturing in response to unstable bladder contractions is common in this group. Many have dysfunctional voiding associated with high voiding pressures and incomplete bladder emptying. Some also have chronic inflammatory changes of the bladder. Historically, endoscopic evaluation of these children often revealed multiple raised "cysts" in the area of the bladder

TABLE 7.10 Bacteriologically verified previous UTI in 7-year-old children

Diagnosis	Girls (%) ($n = 1719$)	Boys (%) ($n = 1834$)
Pyelonephritis	2.7	1.0
Cystitis	3.4	0.3
Unspecified UTI	1.7	0.3
Covert bacteriuria	0.6	0.1
Total	8.4	1.7

neck and trigone. Histologically, submucosal lymphoid follicles were present. Clinically, this entity has been termed cystitis cystica, although the histologic appearance suggests it would be more accurately referred to as cystitis follicularis. The presence of these follicles suggests an immunologic response to chronic infection.[289] It should be noted that treatment of these children is no longer predicated on the basis of these endoscopic findings. Rather, treatment is determined by the recurrence rate of infection and the type of underlying voiding and bowel disorder.

Pyelonephritis

Pathophysiology of Acute Pyelonephritis

APN represents the most serious type of UTI in children. It is not only responsible for greater acute morbidity, but also has the potential for causing irreversible damage. APN in older children typically presents with fever and flank pain or tenderness associated with pyuria and positive urine culture. In the majority of cases, laboratory evaluation reveals an elevated serum WBC count, ESR, and/or CRP. However, when compared directly with localization studies such as DMSA renal scans, these clinical and laboratory parameters are associated with high false-positive and/or false-negative rates.[200] This is particularly true in neonates and young infants, an age group at greatest risk for renal scarring following pyelonephritis. Neonates in particular present with nonspecific symptoms, such as irritability, poor feeding, failure to thrive, vomiting, and diarrhea. Considering that approximately half of all children with febrile UTIs present during the first year of life, the importance of early and accurate diagnosis becomes obvious (Tables 7.11 and 7.12).

Experimental studies by Roberts and others have found that bacterial adherence to uroepithelium elicits an inflammatory cascade proportional to the virulence of the infecting organism. The same acute inflammatory response that is responsible for the eradication of bacteria is also responsible for the damage to renal tissue and subsequent renal scarring.[290] Through a series of experimental studies using the primate model, Roberts has developed a unified theory of the chain of events involved in the process that ultimately leads to renal scarring (Figure 7.7). The initiating event is bacterial inoculation of the renal parenchyma that elicits both immune and inflammatory responses. Whereas either live or heat-killed bacteria can stimulate the immune response, only inoculation by live bacteria causes acute inflammation.[291] Since heat-killed bacteria do not cause renal scarring, it appears that it is the inflammation that is more important as a cause for the subsequent development of permanent renal damage. Potent cytokines induce chemotaxis of granulocytes and cellular- and humoral-mediated bacterial killing.

Studies have also reported that focal ischemia is a consequence of APN. Kaack et al. have shown that granulocyte aggregation within capillaries leads to vascular occlusion. Renal ischemia is then evidenced by a transient rise in circulating renin levels.[292] Hill and Clark found evidence of marked cortical vasoconstriction in areas of acute inflammation in rabbits with acute renal infection, with inflammatory cells obstructing the peritubular capillaries.[293] Androulakakis et al. found microvascular changes in APN in pigs using microradiological and stereomicroscopic techniques. Focal ischemia in areas involved by the acute inflammatory response was evidenced by compression of glomeruli, small peritubular capillaries, and vasa rectae, presumably from interstitial edema.[294] Using the microsphere technique, Majd and Rushton evaluated renal blood flow changes associated with APN in the refluxing piglet model. Focal renal blood flow was decreased in sites of APN identified by diminished uptake of DMSA and subsequently confirmed by histopathology. Uninvolved areas of the affected kidneys demonstrated normal blood flow comparable to that of the contralateral normal kidney.[295]

Since host-derived cytotoxins are central in the genesis of tissue suppuration, investigators have tried to understand and modify the inflammatory response. Granulocytes kill bacteria, releasing toxic enzymes (lysozymes) both within the granulocyte and into the lumen of renal tubules, which causes renal cell damage. The respiratory burst, a phenomenon universal to acute inflammatory responses, generates oxygen radicals (superoxides) that have classically been felt to mediate bacterial killing, as well as that of granulocytes and surrounding tubular cells.[296]

TABLE 7.11 Difference in micturition symptoms in girls with and without former UTI

Symptoms	Former UTI ($n = 75$) %	No History of UTI ($n = 723$) %	p Value
Day wetting	29.3	12.9	<0.0002
Bed wetting	25.3	12.4	<0.002
Prolonged voiding	33.3	17.8	<0.002
Able to void again	32.0	17.3	<0.002
Poor stream	29.3	15.8	<0.003

The role of reactive oxidants, inducible nitric oxide (iNOS), and tissue-destructive proteinases in the acute inflammatory response has also been elucidated.[297] In an extensive review of the literature spanning 70 years, Weiss proposed that neutrophil-derived superoxide and oxygen radicals are merely highly reactive intermediates in the production of toxic chlorinated oxidants (e.g., hypochlorous acid and chloramines). If these chlorinated oxidants are the true mediators of tissue destruction, then inhibiting their generation should lessen tissue injury. In fact, in vitro models have demonstrated that cellular destruction could be prevented in the presence of specific inhibitors of the H_2O_2–halide–myeloperoxidase system, effectively preventing HOCl (hypochlorous acid) generation.[297] Despite this compelling evidence, Weiss's "enthusiasm" for HOCl as the sole agent in inflammation-mediated tissue destruction is tempered by the fact that living tissue perfused with HOCl solutions remains viable.[298] However, evidence suggests that the primary role for HOCl and chloramines is to neutralize circulating enzyme inhibitors that prevent the untimely digestion of host tissues by neutrophils. Thus, in the absence of significant inflammation, any enzymes released from neutrophilic lysosomes are immediately inactivated. However, once stimulated, the neutrophil can release the aforementioned oxidants into its immediate surroundings and can

create a microenvironment capable of inactivating enzyme inhibitors, activating latent neutrophil-derived enzymes, and rapidly degrading microbes, host cells, and connective substratum.[299] Tubular cell death releases the toxic inflammatory agents into the interstitium, causing further damage.

Oxygen radicals are also produced by cell reaction during reperfusion of ischemic tissue. Focal parenchymal ischemia, resulting from intravascular granulocyte aggregation and edema, occurs with bacterial infection of the renal parenchyma.[290,292,296] In ischemic tissue, hypoxanthine is produced during anaerobic metabolism of adenosine monophosphate. During reperfusion, hypoxanthine in the presence of xanthine oxidase and oxygen yields superoxides and hydrogen peroxide.[291] Treatment with allopurinol, an inhibitor of xanthine oxidase, protects against tissue damage from reperfusion injury and inflammatory damage associated with bacteria in the renal parenchyma.[291]

Thus, it appears that the interstitial damage associated with the acute inflammatory response of pyelonephritis results from ischemia-related injury and toxic enzymes. Additionally, bacterial virulence factors, such as hemolysins and lipopolysaccharides, work in concert with neutrophil-derived mediators to disrupt cellular membranes and degrade the extracellular matrix. The inflammatory process extends through the renal interstitium, thus contributing to the damage that ultimately results in irreversible renal scarring.

The impact of adjunctive corticosteroids on postinflammatory renal scarring was evaluated in the treatment of experimental pyelonephritis in the refluxing piglet model (Figure 7.8).[300] The risk of focal scarring corresponded to the severity of the initial acute pyelonephritic lesion, as determined by the percentage of renal parenchyma involved. In kidneys with mild and moderate acute pyelonephritic lesions, antibiotics alone were equally effective in preventing scarring when compared with treatment with antibiotics and steroids. However, severe pyelonephritic lesions were three times as likely to heal without scarring in animals treated with antibiotics in conjunction with steroids when compared with antibiotics alone.

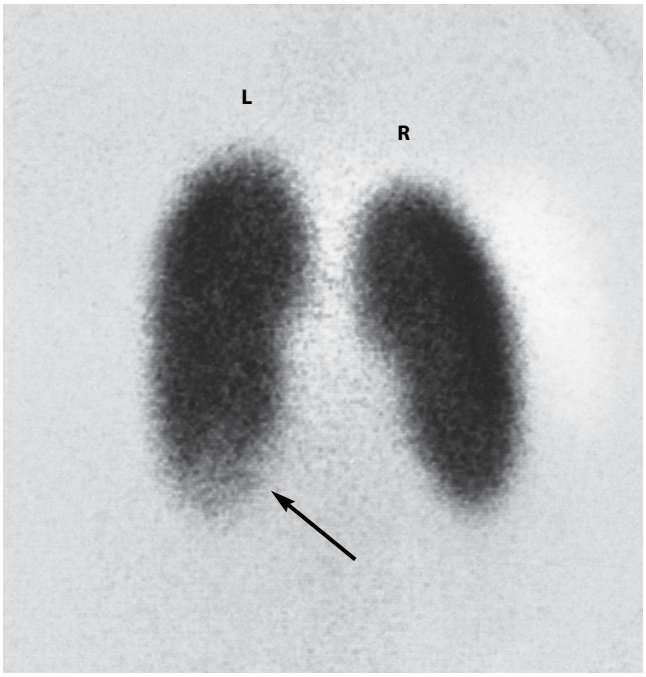

FIGURE 7.8 ^{99m}Tc DMSA renal scan obtained 1 week after introduction of infection in young pig with experimentally produced left vesicoureteral reflux. Focal decrease in uptake with preservation of renal contour is noted in left lower pole (arrow). Pathologic examination confirmed left lower pole pyelonephritis. Detection of Acute Pyelonephritis

Sonography and Intravenous Pyelography

Several clinical studies have clearly demonstrated that renal sonography is not reliable for the detection of APN.[301–307] In one prospective study of 91 children with culture-documented febrile UTIs, DMSA renal scans showed changes consistent with APN in 63% of the patients.[301] In contrast, sonography revealed changes consistent with APN in only 39% of the same patients. More recently, MacKenzie et al. prospectively compared the results of renal ultrasound with those from DMSA renal scans in 112 children with their first documented symptomatic UTI.[302] Although ultrasound was particularly effective in detecting dilatation of the collecting system and renal swelling, it failed to detect more than half of those patients with abnormal DMSA scans demonstrating photon-deficient areas consistent with acute inflammatory changes of pyelonephritis (Figure 7.9). This is supported by other studies demonstrating that sonography fails to identify 50% of renal abnormalities noted on DMSA (Figure 7.9).[301] Intravenous pyelography (IVP) has also been shown to be very insensitive for the detection of APN.[308]

Power Doppler

Brader et al. retrospectively studied a combination of grayscale and amplitude-coded power Doppler renal sonography in children with clinical APN and compared them with DMSA scans.[308,309] Expanding criteria for APN to include changes in flow characteristics on power Doppler, in addition to changes on grayscale sonography, they found combined sensitivities of 92.1% and a specificity of 97.8% and positive predictive value of 88%–92%. This brings into question the idea that a DMSA scan may not be necessary to confirm clinical APN. However, the availability of both pieces of equipment and a properly trained technician may be limited, and these findings need to be substantiated by other investigators.

DMSA Scintigraphy

The diagnosis of APN has traditionally been made on the basis of the classic signs and symptoms of fever and flank pain or tenderness associated with pyuria and positive urine culture. However, accurate diagnosis based solely on these parameters is often difficult, particularly in neonates and infants.[7,310] Despite the fact that the majority of patients (50%–80%) with fever and systemic clinical findings consistent with APN have abnormal DMSA scan

findings, there is still a high false-positive and/or -negative rate based on routine clinical and laboratory parameters, including fever, elevated WBC count, elevated CRP, elevated ESR, and the presence of VUR.[200]

Early clinical reports showed that renal cortical scintigraphy using Tc-99m DMSA or glucoheptonate was significantly more sensitive than intravenous urogram (IVU) and renal sonography in the detection of APN.[311–313] Subsequently, to evaluate the true sensitivity and specificity of renal cortical scintigraphy, experimental studies in an animal model were conducted using strict histopathologic criteria as the standard of reference. When DMSA was matched against histologic controls in an experimental refluxing piglet model, the sensitivity was 87%–89% and the specificity was 100% in both.[314,315] When individual pyelonephritic lesions were analyzed, DMSA scan findings correlated with histopathological changes with an overall agreement rate of 89%–94%. Those lesions not detected were microscopic foci of inflammation not evident on gross examination and not associated with significant parenchymal damage.

Not only is DMSA scintigraphy highly sensitive and specific for the diagnosis of APN, but it also provides important information regarding renal function and the extent of renal parenchymal inflammation. Documentation of renal parenchymal damage associated with APN is fundamental to understanding the roles of infection and VUR in the etiology of pyelonephritis and renal scarring.

Single-Photon Emission Computerized Tomography

The application of single-photon emission computed tomography (SPECT) to DMSA scintigraphy reportedly further enhances the sensitivity of DMSA in the detection of APN.[316–318] In clinical studies, a greater number of defects have been detected by SPECT compared with standard pinhole imaging. Obviously, in these clinical trials, histopathologic confirmation of the abnormal findings demonstrated by renal scintigraphy was not possible. To further evaluate the accuracy of SPECT imaging in the detection of APN, SPECT was compared with pinhole imaging of DMSA renal scans for the detection and localization of APN in 16 piglets (32 kidneys) with bilateral reflux of infected urine.[319] Animals were evaluated with both imaging modalities immediately prior to sacrifice at 1, 2, 3, and 10 days following the introduction of infection into their bladders. The overall sensitivity for detection of affected renal zones with histologic evidence of pyelonephritis was 86% for pinhole imaging and 91% for SPECT. The specificity was 95% for pinhole imaging and 82% for SPECT. The overall accuracy for the presence or absence of kidney involvement was 88% for both (Figure 7.10). Thus, SPECT imaging appears to be slightly more sensitive than standard pinhole imaging, but its application may result in more false-positive findings. Furthermore, it is easier to differentiate acute inflammatory changes from chronic renal scarring with pinhole imaging. Whether pinhole or SPECT imaging is utilized is to some extent dependent on the availability and experience of the imaging unit.

Other Renal Isotopes

The usefulness of an early Tc-99m mercaptoacetyltriglycine (MAG3) renal scan in predicting renal alterations

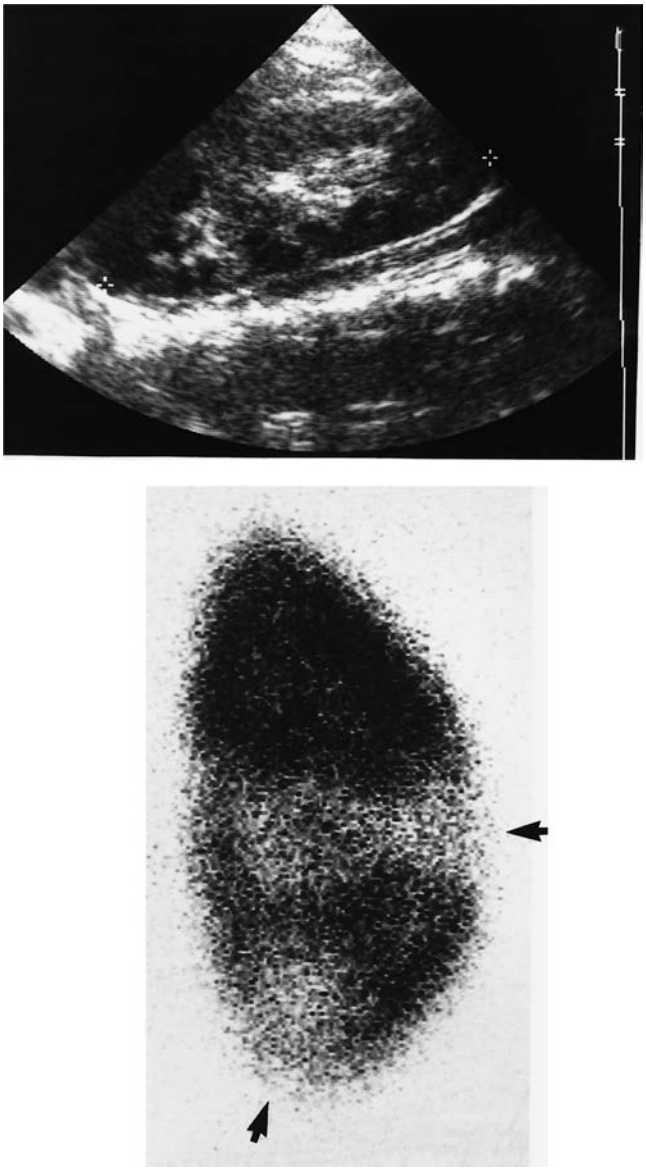

FIGURE 7.9 Normal sonogram and grossly abnormal ^{99m}Tc DMSA renal scan of right kidney showing large mid-zone and moderate lower pole photopenic lesions characteristic of acute pyelonephritis in a 4-year-old girl who presented with her first documented febrile UTI (arrows). VCUG was negative for vesicoureteral reflux.

seen on DMSA renal scans has been evaluated by Piepsz et al.[320] These investigators concluded that the accuracy of the MAG3 renal scan was population dependent. When the DMSA scan was normal or very abnormal, the MAG3 image correctly reflected the findings of the DMSA renal scan. However, when the DMSA abnormalities were less pronounced, the early MAG3 scan failed to detect about half of the cases.

Tc-99m glucoheptonate has also been used in the detection of acute inflammatory changes associated with APN.[312,313,321] Although the sensitivity and specificity of Tc-99m-labeled glucoheptonate and DMSA have not been directly compared, certain observations can be made. Approximately 60% of the administered dose of

99mTc-DMSA is tightly bound to the proximal tubular cells, and only a small amount is excreted slowly in the urine. Consequently, DMSA allows for excellent visualization of the renal parenchyma without interference from retained tracer in the collecting systems. In contrast, only about 20% of the administered dose of Tc-99m glucoheptonate is firmly bound to the tubular cells. Most of the administered dose is excreted in the urine, which allows for moderately good visualization of the renal collecting systems on the early images. This additional information makes glucoheptonate the preferred agent of some clinicians.[319] However, the quality of the delayed renal cortical images is clearly better with DMSA.

CT Scans and MRI

Computed tomography (CT) scans have become prevalent throughout most areas of medical care in the United States and have been shown to be an accurate imaging modality for the detection of acute pyelonephritic inflammatory changes in the renal parenchyma. The clarity of the images and the speed at which the test can be performed are utilized in many emergency rooms for rapid assessment and diagnosis. However, more recently the usage of CT scans has come into question within the medical community for the risk of radiation exposure to patients, as well as the increased cost to the healthcare system.

Many institutions are conducting risk–benefit analysis for CT scan radiation dose. At this time, in the United States it is estimated that only 40% of CT scanners are accredited.[322] The total dosage of radiation that puts someone at higher risk for oncologic side effects is also being debated. In the pediatric population in particular, there are concerns that some settings for dosage safety are not appropriately adjusted to weight-based criteria. Legal enforcement of regulation is beginning in some states. For instance, starting in July 2012 California state law requires radiologists to record the dose of radiation each patient receives.[320]

Consequently, CT scans are not considered to be the standard of care of pediatric patients with uncomplicated clinical pyelonephritis. It is useful for patients with equivocal ultrasound findings suspicious for renal abscesses. At many centers, magnetic resonance scans are recommended prior to CT scans in attempts to reduce radiation risk. In a clinical study for the detection of acute pyelonephritic damage in children, the sensitivity and specificity of gadolinium-enhanced MRI was equal to that of Tc-99m DMSA scanning.[323] In an experimental refluxing infected piglet model, SPECT imaging using DMSA was compared with spiral CT scanning (pre- and postcontrast), gadolinium-enhanced MRI, and power Doppler sonography in 35 infected piglets with 70 refluxing kidneys.[324] The imaging modalities were interpreted independently and compared in a blinded fashion with histopathologic findings. SPECT DMSA, spiral CT, and MRI had similar sensitivity and reliability for the detection and localization of APN, whereas power Doppler sonography was significantly less accurate (Figures 7.11 and 7.12). A distinct benefit of MRI is that it excels at tissue differentiation and can provide an estimate of renal function without ionizing radiation or iodinated contrast media.

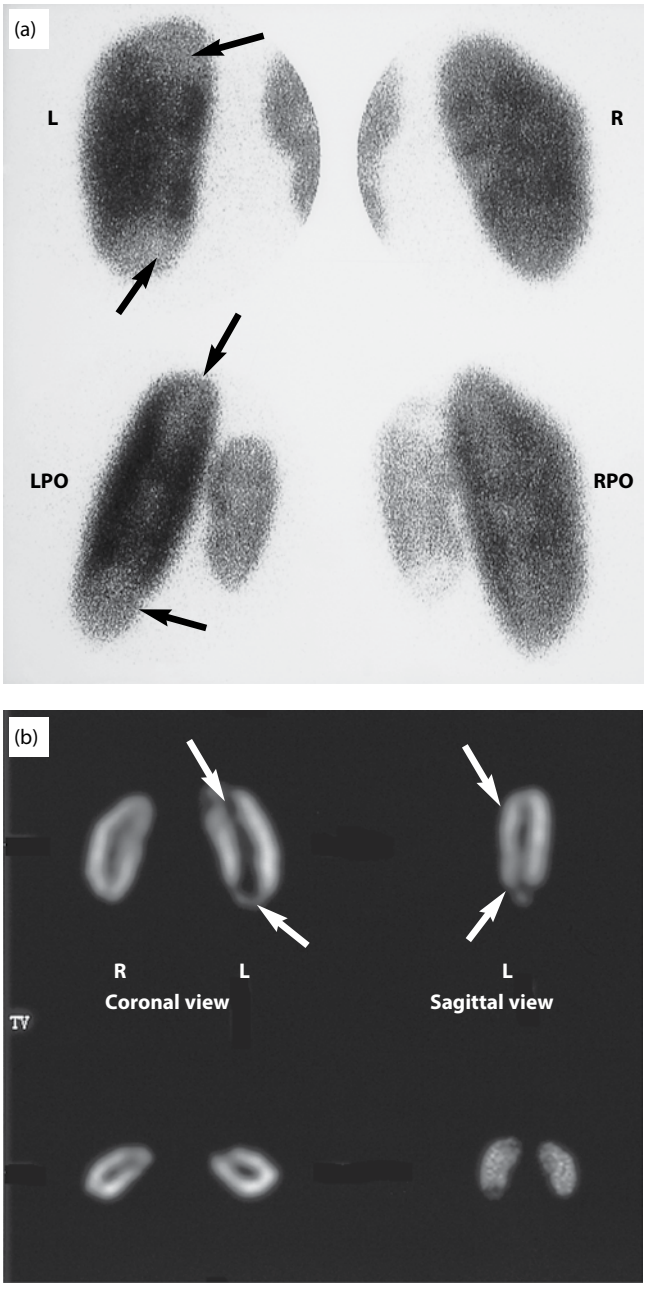

FIGURE 7.10 (a) Posterior and posterior oblique pinhole and (b) coronal and sagittal SPECT images of ^{99m}Tc DMSA renal scan in a young pig with bilateral vesicoureteral reflux and acute left pyelonephritis 48 h after introduction of *E. coli* broth into the bladder. Photopenic lesions in the left upper and lower poles are demonstrated by both modalities (arrows).

EVALUATION OF THE CHILD WITH URINARY TRACT INFECTION

Controversy continues to exist regarding when and how a child with documented UTI should be evaluated. A recent systematic overview of the literature to assess the evidence on which current recommendations for routine diagnostic imaging are based found that there were no controlled trials or analytic studies that evaluated the need for routine

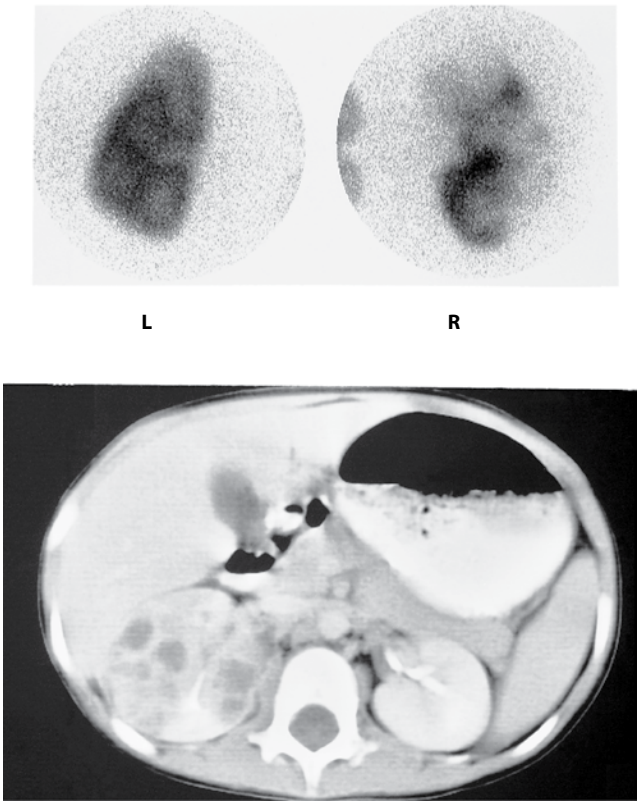

FIGURE 7.11 Severe multifocal acute pyelonephritis in the right kidney is well demonstrated on both a ^{99m}Tc DMSA renal scan and CAT scan in a 3-year-old girl with her first febrile UTI. Photopenic areas on DMSA scan correspond to attenuated hypodense lesions on CAT scan. Note diffuse right renal swelling on CAT scan.

FIGURE 7.12 Gadolinium-enhanced MRI in a young pig with bilateral vesicoureteral reflux (VUR) demonstrates multiple acute pyelonephritic lesions in both kidneys as evidenced by bright parenchymal lesions (arrows).

diagnostic imaging.[325] All reports were descriptive, and the majority were retrospective. Furthermore, none provided evidence of the impact of routine imaging on the development of renal scars and clinical outcomes in children with their first UTI.

Most pediatric urologists would agree that children under 5 years of age and boys of any age with febrile UTI or documented APN should be evaluated when infection is first recognized, to determine if further testing is needed. The key to this recommendation is adequate documentation of UTI.

The arguments in favor of early evaluation of young children following their first documented febrile UTI are based on both experimental and clinical data. Clinical and experimental studies have proved that significant renal scarring can occur after a single febrile UTI.[326,327] Furthermore, a higher incidence of renal scarring has been reported in children with VUR and recurrent UTIs than in those who have had only a single infection.[5,181,328,329] In the presence of a UTI, VUR increases the risk of pyelonephritis compared with those without VUR.[201] Recurrence of UTI within 1 year of a preceding infection occurs in approximately 30% of girls with one, 60% with two, and 75% with three prior infections.[17] Furthermore, the nonspecificity of signs and symptoms that typically accompany urinary infection in infants and toddlers often makes it impossible to determine whether an infection actually represents the first episode.[17] Additional justification for early evaluation is based on the high yield of uropathology obtained from the evaluation of children with culture-documented UTIs. Cystography in Caucasian girls with symptomatic UTIs consistently demonstrates the presence of VUR in approximately 30%–50% of cases, regardless of whether the study is requested by pediatric subspecialists (urology or nephrology) or other clinicians (pediatricians, family practitioners, or adult urologists).[5,197,330] The exception is found in African American girls with UTI, in whom the relative incidence of VUR is about one-third that of Caucasian girls.[27,63] Unfortunately, other clinical parameters have proved unreliable in distinguishing those children with UTI who also have VUR.[219] All the aforementioned factors offer a convincing argument to pursue early evaluation of young children following their first documented UTI. Waiting until a child has had two or more UTIs before proceeding with evaluation may increase the risk that permanent scarring, which might have otherwise been prevented, may occur. However, recent research demonstrated that routine cystography in every child after first febrile UTI is a nonselective, painful, irradiating, and expensive test with risk of iatrogenic UTI.[254,256,257] These randomized prospective studies have failed to demonstrate a reduction in recurrent febrile UTIs or renal scarring in patients with grades I–III VUR treated with low-dose antibiotic prophylaxis versus those followed expectantly after their first febrile UTI.[266,331] In contrast, a therapeutic benefit of antibiotic prophylaxis over a monitored surveillance program was demonstrated in the recently completed multi-institutional Swedish Reflux Trial that evaluated 203 children less than 2 years of age with grades III and IV VUR. A significant reduction of febrile UTI recurrences and new renal damage was observed in girls treated with antibiotic prophylaxis.[332]

Thus, the role of routine (invasive) cystography in all children is questioned since in the majority, who have low-grade VUR, voiding cystourethrography (VCUG) does not influence long-term outcome and management.[332,334] The counterdebate is that a subset of high-risk patients will be missed. Therefore, research is needed and ongoing to develop a more highly selective, evidence-based approach to predict which children are at high risk for febrile UTI and renal scarring.

History

Evaluation of the child with a UTI should always begin with a careful history. Because bladder emptying plays an important role in the etiology and prevention of UTI, a careful voiding history is an essential component of the workup of toilet-trained children with UTIs.[335] Many of these children also have associated constipation that may only be detected when specific questions are directed toward the patient and parents. Family history should also be obtained since heredity appears to play a role in an individual's predisposition toward infection, as evidenced by familial studies showing an increased incidence of bacteriuria in female siblings.[25] Similarly, a significant familial risk for VUR has been demonstrated when a sibling or parent has a history of having reflux.[336,337]

Physical Examination

Physical examination of the child presenting with UTI should include palpation of the abdomen for flank masses, bladder distension, and/or abdominal masses caused by fecal impaction. Although genital examination in boys should exclude significant meatal stenosis, this is an extremely rare cause of UTI. Considering the epidemiological evidence demonstrating an increased risk for UTI in uncircumcised boys, the circumcision status is of particular importance in male infants with a history of UTI. Abnormal genital findings in girls include vulvovaginitis or the presence of labial adhesions that might predispose the child to perineal colonization by bacteria. More often, labial adhesions increase the risk for contamination of "clean-catch" urine specimens for culture. In children with a significant history of voiding dysfunction associated with constipation and/or encopresis, a brief neurologic examination should include evaluation of perineal sensation, of peripheral reflexes in the lower extremities, and of the low back for sacral dimpling or cutaneous abnormalities that might suggest an underlying spinal abnormality (occult spinal dysraphism). Rectal examination for fecal impaction may be indicated in select patients if the history suggests severe constipation or encopresis, although this is rarely necessary.

Imaging

Recommended imaging studies for a child with a history of a culture-documented UTI are based, to some extent, on the experience of the radiologist and the availability of imaging modalities. Age, gender, race, and the type and frequency of UTIs must also be taken into consideration. For many years, the emphasis on the investigation of the child with UTI has centered on diagnosis of VUR. More recently, some authors have suggested that the emphasis should be focused on whether the child has renal scarring or is at risk for renal scarring.[338–343] Those favoring this "top-down" approach argue that if there is no evidence of renal damage at the time of the infection, then it is not necessary to evaluate for VUR, as the risk for future renal scarring is minimal. Consequently, these authors have recommended that the initial evaluation in children should be of the kidney, including sonography to exclude surgical conditions that predispose to infection and DMSA scintigraphy to detect acute pyelonephritic inflammation. With this approach, cystography is reserved for children with abnormal DMSA scan findings or recurrent UTIs. In contrast, most American urologists still prefer a "bottom-up" evaluation of infants and toddlers that always includes a cystogram to detect the presence of VUR, ureteroceles, posterior urethral valves in boys, or bladder wall thickening, along with a sonogram to look for obstruction, hydronephrosis, or other congenital malformations.[344,345]

Whether or not one accepts the recommendation that DMSA scintigraphy should precede VCUG in the evaluation of children with UTIs is determined in part by the goal of management of these patients. For those whose ultimate goal of treatment is the cessation of VUR, when present, VCUG will continue to be the initial study of choice. For others, whose primary goal is the detection and future prevention of pyelonephritis and new renal damage, DMSA scintigraphy may well replace VCUG as the initial investigation of children with symptomatic UTIs. MRI is currently expensive, not readily available at all institutions, and generally requires sedation for small children. Consequently, it is not used routinely for the diagnosis of febrile UTIs at this time.

Timing of Evaluation

The timing of evaluation is often a concern of the urologist, radiologist, and pediatrician. Many recommend that children requiring hospitalization should at least be screened for obstruction with an ultrasound scan prior to discharge. For those patients being evaluated with cystography, it has been suggested that this be delayed 4–6 weeks following the acute infection to avoid demonstrating transient mild reflux secondary to inflammatory changes of the ureterovesical junction. However, it is rare for reflux to be detected during infection and then disappear after treatment.[346,347] Furthermore, since the significance of reflux is greatest at the time of bacterial infection, demonstration of even transient reflux may be very meaningful. One potential disadvantage of obtaining a cystogram early in the course of a febrile infection is that ureteral dilatation secondary to the effect of endotoxins may result in overestimation of the grade of reflux.[52,348] Nevertheless, a prolonged "waiting period" is not necessary. The cystogram, when indicated, usually can be performed whenever the patient is no longer symptomatic and when the urine is sterile.[349] Regardless of when studies are performed, antibiotic prophylaxis should be considered until that time, particularly in infants or in children with a previous febrile UTI, in order to prevent reinfection.[327,349]

For patients evaluated with DMSA renal scintigraphy, the timing of the study is in part determined by the reason for the study. If one is attempting to document acute pyelonephritic inflammatory changes, the DMSA renal scan is best obtained early, within the first several days of the acute episode.[350] However, if the primary goal is to document irreversible renal scarring following an episode of infection, then the study should be delayed for 6 months following the acute infection since transient acute changes on DMSA scans can persist for up to 5 months prior to resolving.[351]

Lower Tract Imaging

Both direct and indirect cystography techniques have been used to evaluate for VUR. Direct cystography involves filling the bladder by urethral catheterization or percutaneous suprapubic infusion. Both standard contrast medium and radiolabeled nuclides are satisfactory. In boys, contrast cystography is preferred because it provides for visualization of the urethra and for grading reflux (Figure 7.13). It is also more reliable for detecting duplication, ureteral ectopia with or without ureteroceles, posterior urethral valves, bladder trabeculation, bladder diverticula, and foreign bodies. Many also prefer its use for the initial examination in girls because the grade of reflux can be determined. Historically, several methods for grading were used; however, the International Reflux Study method is most widely accepted (International Reflux Committee 1981).[352,353] A disadvantage of standard contrast cystography is the high gonadal radiation dose it entails, particularly with multiple studies or fluoroscopic monitoring. The addition of digital fluoroscopy reduces gonadal radiation exposure.[354] Using a low-dose fluoroscopic system with a computer-based video frame grabber, researchers have reported that the ovarian radiation dose compares favorably to radionuclide cystography.[355]

Direct radionuclide cystography allows continuous monitoring for reflux throughout the study without

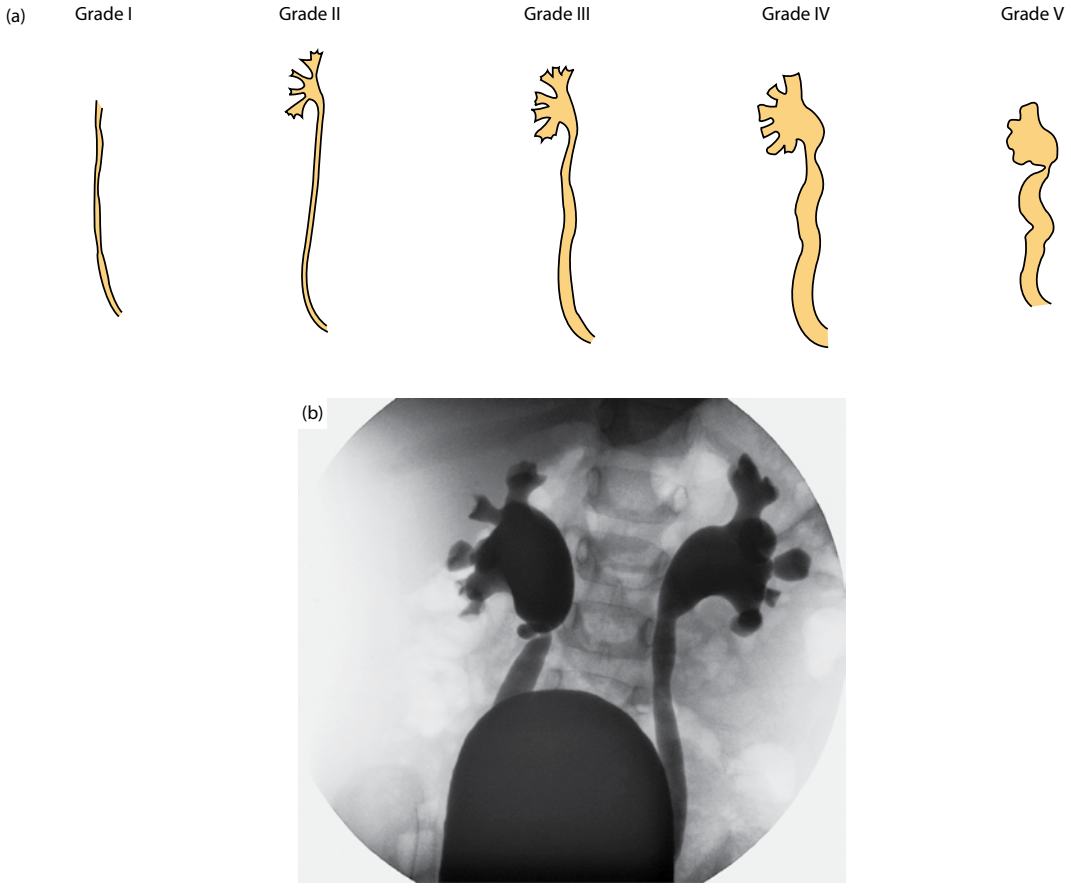

FIGURE 7.13 (a) International classification of vesicoureteral reflux: grade I, ureter only; grade II, ureter, pelvis, calices, no dilatation, normal caliceal fornices; grade III, mild or moderate dilatation and/or tortuosity of ureter, and mild or moderate dilatation of the pelvis, but no or slight blunting of the fornices; grade IV, moderate dilatation and/or tortuosity, of ureter and mild dilatation of renal pelvis and calices, complete obliteration of sharp angle of fornices but maintenance of papillary impressions in majority of calices; grade V, gross dilatation and tortuosity of ureter, gross dilatation of renal pelvis and calices, papillary impressions are no longer visible in majority of calices. (b) Voiding cystogram shows grade III VUR on the right with moderate dilatation and tortuosity of ureter, moderate dilatation of the pelvis, but slight blunting of the fornices. Grade IV reflux is seen on the left with similar dilatation of the ureter and pelvis but with obliteration of sharp angle of fornices. Papillary impressions are maintained in the majority of the calices. ([a] Modified from International Reflux Committee. Medical versus surgical treatment of primary, vesicoureteral reflux. *Pediatrics* 1981;67:392.)

additional radiation exposure. It is reported to be more sensitive than contrast cystography for the detection of reflux.[356–358] Whereas precise grading of VUR is limited, it usually can be categorized as mild, moderate, or severe (Figure 7.14). Although radionuclide cystography has been criticized for being unable to detect grade I/V VUR, one study found that direct radionuclide cystography demonstrated VUR to the renal pelvis in all 17 kidneys with grade I/V VUR on contrast cystography, again suggesting a higher sensitivity for detection of VUR.[359] The radiation dose from radionuclide cystography is reportedly less than that with standard techniques using contrast cystography, making it ideal for the follow-up of children with VUR and for following the results of antireflux surgery.[360]

Indirect radionuclide cystography uses Tc-99m diethylenetriaminepentaacetic acid (DTPA), which is excreted by glomerular filtration. The presence of reflux can be assumed when radioisotope counts increase in the renal areas after voiding. Indirect cystography is less reliable for the detection of VUR than direct radionuclide cystography, with false-negative rates ranging from 22% to 51%.[361,362] One study comparing indirect radionuclide cystography using Tc-99m MAG3 with direct cystography reported that indirect cystography was unreliable for the detection of VUR, missing approximately two-thirds of refluxing kidneys (Figure 7.15).[362] The positional instillation of contrast (PIC) cystogram is an alternative method for detecting occult VUR. It is performed under general anesthesia in the operating room with contrast instilled via cystoscope at the ureteral orifices. It has been used to detect occult VUR that standard VCUG and nuclear cystogram failed to detect. Although there are some proponents of PIC cystograms, the significance of this iatrogenically created VUR has been questioned by many, and the above-mentioned modalities for VUR identification are sensitive without the use of anesthesia.[363]

Upper Tract Imaging

Recommendations for evaluating the upper urinary tract in children presenting with UTI also vary from institution to institution. The ideal study should be painless, safe, cost-effective, and associated with minimal or no radiation, and yet should be capable of detecting clinically significant structural malformations, as well as renal scarring. Unfortunately, such an all-encompassing study does not exist.

One approach is the initial screening of all patients being evaluated for a history of UTI with a renal bladder sonogram.[364] Sonography is painless, noninvasive, simple to perform, radiation-free, and independent of renal function. It is critical that appropriate images of the ureters, bladder, and true pelvis be routinely obtained in order to detect the presence of ureteroceles or dilated ureters secondary to ureteral ectopia, ureterovesical junction obstruction, or severe VUR. To do so, the bladder should be full during the examination. A postvoiding residual can also be demonstrated at the completion of the study. In children, sonography has been found to be as sensitive as IVP for the detection of any significant renal abnormality except for uncomplicated duplication anomalies and focal renal scarring.[364–367] However, based on review of the literature, the sensitivity of renal ultrasound for predicting renal scarring has been reported to be 26.7%–41% with low positive predictive values. The sensitivity of ultrasound to predict the presence of VUR has been reported to be 65%–87%.[368] Lee et al. found that the sensitivity of ultrasound alone for predicting VUR in children less than 2 years of age was 70.1%. When renal ultrasound was combined with DMSA, the sensitivity increased to 83.6%.[369] In other retrospective studies, it has been demonstrated that only 22.8% of renal parenchymal defects demonstated by DMSA scans were detected with ultrasound.[370]

In the absence of reflux, hydronephrosis revealed by sonography is best evaluated with diuretic renography using Tc-99m DTPA or Tc-99m MAG3.[371] When combined with the findings of the renal bladder sonogram, the site of obstruction can be reliably determined in almost all cases.[104] When needed, further evaluation is best accomplished with percutaneous antegrade pyelography and pressure perfusion studies (Whitaker test).

Considering the very low incidence of surgically significant hydronephrosis presenting as UTI, some authors have questioned the role of sonography in the investigation of UTIs in children, recommending instead a cortical renal scan as the initial upper tract study of choice.[302,321,372,373] Still other authors have suggested a tailored approach to the evaluation of children with UTI, beginning with a voiding cystogram.[374,375] If no reflux is present, a renal ultrasound scan is done to exclude hydronephrosis or other upper tract malformations. Otherwise, if reflux is demonstrated, the next study would be a renal cortical scan to detect renal scarring (Figure 7.16).

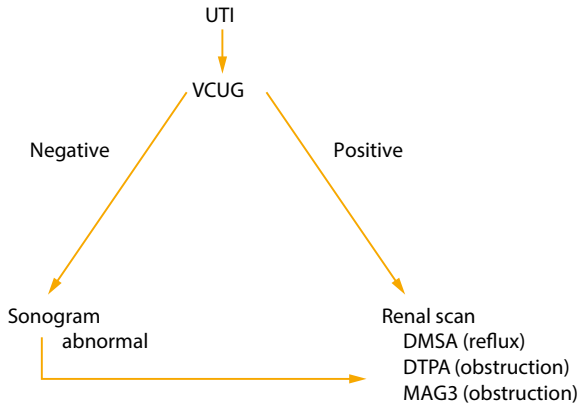

FIGURE 7.16 Algorithm for evaluation of children with urinary tract infection. (Adapted from Rushton HG. Genitourinary infections: nonspecific infections. In: Kelalis PP, King LR, Belman AB, eds. *Clinical Pediatric Urology*, 3rd edn. Philadelphia: WB Saunders, 1992. With permission.)

In clinical practice, the use of DMSA scintigraphy is best reserved for those occasions when it will influence management. DMSA scintigraphy can be helpful in the initial evaluation and follow-up of patients with VUR. For example, not all patients with VUR and breakthrough UTIs require immediate surgical intervention, particularly those with ABU (Figure 7.17).[376] In contrast, when new renal damage associated with a breakthrough UTI is objectively demonstrated by DMSA scintigraphy, antireflux surgery becomes imperative (Figure 7.18). Likewise, DMSA scintigraphy is important in the initial evaluation of infants with prenatally detected VUR, as many of these patients will have significant congenital reflux nephropathy.

DMSA scintigraphy is also particularly helpful for establishing the correct diagnosis of pyelonephritis in situations when the diagnosis is unclear based on clinical and laboratory findings, such as in neonates and young infants. Not infrequently, the diagnosis in these young children is obscured by improper urine collection techniques or the institution of antibiotics before a urine culture is obtained. Other difficult diagnostic situations include children with neuropathic bladders managed by clean intermittent catheterization.[377,378] These children are usually chronically bacteriuric; therefore, the diagnostic significance of a positive urine culture at the time of a febrile episode is lost.

Top-Down versus Bottom-Up Debate

The ideal approach to the initial radiological evaluation of children with UTI is in debate. The conventional bottom-up approach of cystography combined with sonography of the upper urinary tract, with its focus on the detection of all upper and lower tract abnormalities, is being challenged by the top-down approach, which focuses on confirming renal parenchymal involvement to identify patients who should undergo further investigation by cystography. The goal of the top-down approach is to minimize unnecessary interventions for clinically insignificant VUR and improve compliance with recommended testing.[368] Studies have

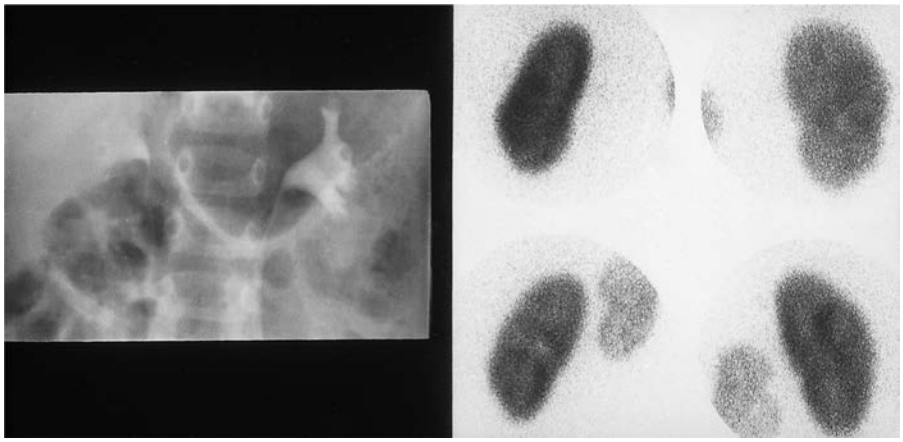

FIGURE 7.17 A 3-year-old girl with bilateral grade II vesicoureteral reflux (*left*) developed a breakthrough febrile UTI while on antibiotic prophylaxis. A ^{99m}Tc DMSA renal scan (*right*) at the time of the infections did not demonstrate any evidence of pyelonephritis or scarring. Her prophylaxis was changed and repeat isotope cystogram 1 year later revealed complete resolution of her reflux.

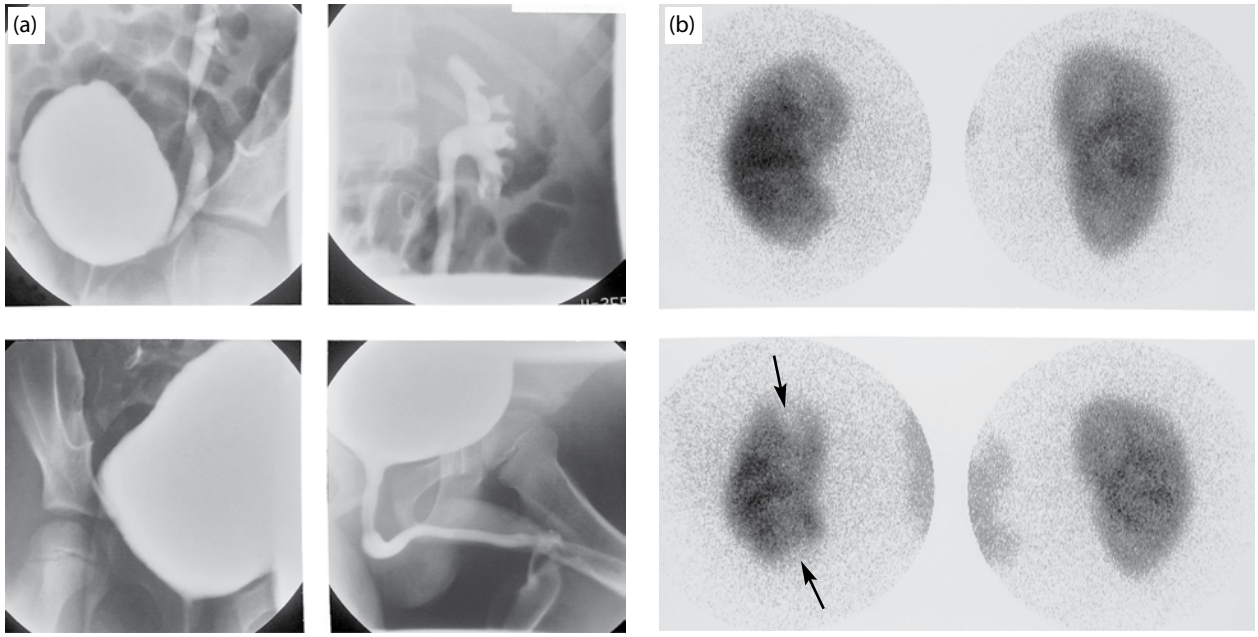

FIGURE 7.18 A 2-year-old girl presented with her first culture- documented UTI. (a) Voiding cystogram demonstrates left grade III vesicoureteral reflux. (b) (*Top*) Initial ^{99m}Tc DMSA renal scan was normal. (*Bottom*) Repeat ^{99m}Tc DMSA renal scan following a breakthrough febrile UTI reveals acute pyelonephritic changes in the left upper and lower poles (arrows). Left ureteral reimplantation was performed.

shown that compliance for follow-up imaging in infants diagnosed with febrile UTI is less than half.[379]

Traditionally, the goal of radiographic evaluation was to identify all patients with VUR; however, with the recognition that VUR is a spectrum disease, the recent shift in philosophy is to identify those subsets of patients that have clinically significant VUR based on radiological confirmation of renal involvement at the time of the UTI, as it is this group of patients who are thought to be at higher risk for renal scarring.[368] This top-down approach could potentially eliminate getting a VCUG in up to half of patients presenting with a febrile UTI and, at the same time, avoid overtreatment of those patients with clinically insignificant VUR.[380]

Mantadakis et al. performed a meta-analysis to address the controversy over what imaging needs to be performed following a first febrile UTI. They concluded that acute phase DMSA renal scintigraphy cannot be recommended as a replacement for VCUG evaluation of young children with first febrile UTI due to the fact that DMSA scans have limited ability to identify all patients with VUR.[381,382] However, several other studies suggest that children with a negative DMSA renal scan during their first febrile UTI rarely have high-grade VUR, suggesting that VCUG can be avoided in children with a negative DMSA.[380,383–386] Lee et al. pooled retrospective data from January 2001 through May 2007 in children younger than 2 years of age with first febrile UTI, comparing the sensitivity of ultrasound and DMSA scans for the diagnosis of VUR. They reported an aggregate sensitivity of DMSA scanning for identifying dilating VUR of 60% and a specificity of 65%.[369] Meanwhile, in a prospective study of 250 patients with first-time febrile UTIs who were evaluated within 2 weeks with a DMSA renal scan, Preda et al. reported a sensitivity of 96%, specificity of 55%, and negative predictive value of 99% for the detection of grades III–V VUR.[380] Herz et al. prospectively evaluated 121 children with febrile UTIs with both an acute phase DMSA at the time of infection and a repeat DMSA scan at 6 months. The acute phase DMSA scan had an odds ratio of 35.4 for the prediction of clinically significant VUR, defined as grade III or higher, or VUR associated with subsequent recurrent UTI and/or renal scarring. The acute phase DMSA scan had a sensitivity of 96%, specificity of 72%, positive predictive value of 83%, and negative predictive value of 92% for the detection of clinically significant VUR, whereas the late phase DMSA scan at 6 months had a sensitivity of only 26%.[387] Similarly, studies by Coulthard et al. and Rushton reported that more than 90% of children with grades III–V VUR demonstrated acute changes on DMSA scans.[388,389] The question becomes, what is the clinical significance of missed VUR on DMSA scan? Studies have demonstrated that patients with normal DMSA scans and higher grades of VUR who were followed had resolution or downgrading, and no new renal scarring on follow-up.[369]

One argument against using DMSA scintigraphy for the evaluation of VUR is that it is more costly than VCUG; however, it has been shown that effective use of the top-down approach in children with febrile UTI can be cost-efficient, particularly when one considers that patients evaluated with VCUG also need to undergo sonography. Furthermore, additional cost reduction with the top-down approach is achieved by avoiding unnecessary treatment and follow-up imaging of patients with clinically insignificant low-grade VUR and/or negative DMSA scans.[390] A limitation of the method, though, is that it is a more time-consuming test with technical limitations, including

the need for special equipment and skilled staff for accurate performance and interpretation.[381] In a pilot study for the Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) investigation, the methodology and image quality for DMSA scintigraphy varied between institutes despite the dissemination of methodology guidelines.[391] Seventeen percent of studies were rejected for quality issues, with the most common reason being poor image quality. Another consideration is that many younger children need to undergo sedation to avoid motion artifacts, although sedation is now also being routinely used at many pediatric hospitals for VCUGs. The overall radiation exposure is higher with DMSA scintigraphy than with fluoroscopic VCUG; however, the gonadal radiation is lower.[227,368]

Preliminary data indicate that MRI could replace DMSA scan as the renal imaging of choice after febrile UTI, as well as providing a modality for the detection of VUR, thus obviating radiation exposure.[392] Coronal fat saturated T1-weighted sequences are best for detecting renal parenchymal defects. The sensitivity of MRI for the detection of APN ranged from 77% to 100%, and the specificity ranged from 78% to 91%, when compared with DMSA scintigraphy.[393,394]

Chang et al. investigated the ability of MRI as a quantitative modality to detect renal parenchymal damage in children with VUR and UTIs.[395] Renal damage was characterized by renal scarring and grossly shrunken kidneys. The study showed a direct association between renal parenchymal loss and increasing VUR grade (nonrefluxing, low-grade VUR, and high-grade VUR). They found no significant difference between renal volumes in kidneys that demonstrated spontaneous resolution of VUR on follow-up when compared with controls. However, renal volumes for children who underwent surgical intervention were significantly decreased compared with normal controls and kidneys that exhibited spontaneous resolution.[395] At the present time, the use of MRI is limited in children by the expense of the study, the routine need for sedation, and the lack of availability of expertise or capacity in many hospitals.

In the future, the top-down approach could be even further refined by the use of biomarker profiles, such as PCT, CRP, and/or IL-8, to detect acute renal parenchymal involvement, which could then be used to select those patients who should then undergo further evaluation with appropriate imaging.

Radiation Exposure

Radiation exposure from imaging techniques is a rapidly expanding area of research. The ideal diagnostic exams would have high sensitivity, high specificity, and low radiation exposure, and be minimally invasive. The risk of cancer from radiation is actively being investigated in the adult CT literature.[396] The cost–benefit ratio of MRI versus CT scan radiation exposure is an ongoing debate in the adult literature. The radiation exposure from fluoroscopy has also been the subject of investigation.[397] With new advancements in fluoroscopy, the radiation exposure with variable-rate pulsatile fluoroscopy is reportedly 10 times less than that of the traditional continuous fluoroscopic units and 5 times less than that of a DMSA scan.[398] It must also be taken into consideration that although the DMSA scan has more radiation exposure than variable-rate fluoroscopy, the kidneys are the primary area of exposure in the DMSA scan and are known to be relatively radioresistant. In contrast, the primary area of exposure from a VCUG includes the gonads.

Renal Scarring

Partly because most renal scars that are detected in children with prior UTIs have become established by the time of initial evaluation, the pathogenesis of renal scarring remains controversial.[281,282,328] Furthermore, it has become increasingly clear that the term *renal scarring* has been applied to the end result of more than one type of pathophysiological process, including both abnormalities that are congenital and those that are acquired postnatally. The correlation between the severity of VUR and renal scarring is also well established.[5,399–401] Although the vast majority of cases of renal scarring associated with VUR are detected during the evaluation of children with UTI, studies of prenatally detected hydronephrosis secondary to high-grade VUR also have confirmed cases of congenital functional abnormalities documented by DMSA renal scintigraphy, even in the absence of infection (Figure 7.19).[402–407] Furthermore, a higher prevalence of renal scarring has been reported in children with secondary VUR associated with functional or anatomical bladder outlet obstruction, including posterior urethral valves and neuropathic bladders, than in children with primary VUR.[65] Lumping renal sequelae from all these pathophysiologic entities under the terms *renal scarring* or *reflux nephropathy* has hampered attempts at understanding the pathogenic mechanisms involved.

The critical role that infection plays in the pathogenesis of acquired renal scarring associated with reflux was clarified in Ransley and Risdon's classic experimental studies of VUR in piglets.[408] In the face of VUR and normal voiding pressures, renal scarring occurred only when urinary infection was present. In the absence of infection, renal changes only occurred when VUR was associated with increased bladder outlet resistance, so that obstruction, not reflux, was the pathophysiologic explanation for renal damage. Portions of the kidney at risk for scarring were those susceptible to pyelotubular backflow (intrarenal reflux) based on papillary morphology and configuration (Figures 7.20 and 7.21).

Clinically, new or progressive scarring is almost always associated with a history of UTI. Experimental studies and clinical experience have shown that even a single episode of pyelonephritis can lead to significant renal damage (Figure 7.22).[326,409] Furthermore, a clear association between the number of pyelonephritic attacks and incidence of renal scarring has been reported (Figure 7.23).[5,23,327,329] Both experimental and clinical studies have also shown that some renal scarring can be prevented or diminished by early antibiotic treatment of APN (Figures 7.24 and 7.25).[40,326,410,411] Conversely, a delay in antibiotic therapy is associated with an increased risk of DMSA scan–demonstrated APN.[412,413] Furthermore, when reflux is present, progressive renal scarring can be successfully prevented by

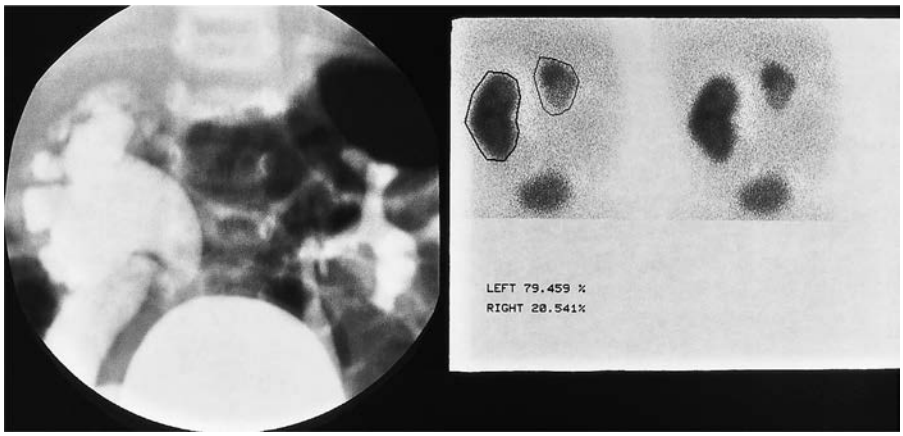

FIGURE 7.19 One-month-old boy with prenatally detected hydronephrosis. (*Left*) Voiding cystogram shows right grade V (note intrarenal reflux) and left grade III vesicoureteral reflux. (*Right*) ^{99m}Tc DMSA scan reveals a hypoplastic right kidney with markedly reduced differential renal function. He had been on antibiotic prophylaxis since birth and urine cultures were negative.

keeping the patient free of infection.[400,401,414] Based on all the above, it is clear that infection, not reflux alone, is a prerequisite for acquired renal scarring.

Congenital reflux nephropathy associated with reflux

Severe reflux may be associated with significant renal dysplasia or hypoplasia thought to result from abnormal induction of the nephrogenic cord during embryogenesis.[415,416] Several reports have described DMSA scan renal functional abnormalities in patients with primary VUR detected prenatally.[402–406,417] The reported incidence of renographic abnormalities in these studies has varied widely, ranging from 17% to 60%.[402,403,405] Many of these infants were evaluated by renal scintigraphy prior to any known episodes of infection, confirming that the functional abnormalities present at birth represent a congenital abnormality of the renal cortex rather than one that is acquired. In one study, nephrectomy specimens in a few of these severely "scarred" kidneys with minimal function demonstrated severe dysplasia and growth arrest.[405]

Congenital reflux nephropathy is a pattern of impaired renal function and development that is particularly associated with high-grade VUR, especially males.[418] Mechanisms of developmental disruption are potentially related to VUR dynamics during gestation and associated bladder dynamics that continue into postnatal life. Congenital damage is often dysplasia that may be a result of disordered renal development secondary to significant alterations in bladder dynamics.[419] In other cases, the kidneys are hypoplastic but do not demonstate focal defects,

which may represent altered renal parenchymal development due to an abnormal or ectopic ureteral bud. In contrast, acquired damage associated with febrile UTI is the dominant etiology for renal scarring in girls.[420]

New or Acquired Scarring

Numerous studies have documented a link between UTI, VUR, and renal scarring with VUR considered to be a major risk factor for pyelonephritis and renal scarring.[421] Studies estimate that patients with high-grade VUR are 4–6 times more likely to have scarring than those with low-grade VUR, and 8–10 times more likely than patients without VUR.[329,345]

Until recently, a common assumption was that VUR was an absolute prerequisite for new or acquired renal scarring. This mind-set was further perpetuated by earlier investigations of new or acquired renal scarring, most of which focused retrospectively on patients with known VUR. However, in one earlier study that selected patients on the basis of infection alone, only half of the 37 children who formed new renal scars had VUR.[411] While the presence of VUR increases the risk of developing APN should UTI occur, thereby contributing to an increased risk of subsequent renal scarring, VUR by itself is not required for APN or for renal scarring.[63,422]

Several investigators have now evaluated the evolution of the acute inflammatory changes associated with pyelonephritis using serial DMSA renal scans.[351,423–426] The interval from the initial DMSA scan obtained at the time of acute infection until the repeat scan ranged from 3 months to 2 years. In one review, acute DMSA renal scan defects persisted as renal scarring in 36%–52% of kidneys.[389] The sites of new renal scarring corresponded exactly to those sites of APN seen on the initial DMSA renal scans, confirming the primary role of the acute inflammatory response to infection in the etiology of acquired renal scarring (Figure 7.26). Contralateral normal kidneys and initially uninvolved areas of abnormal kidneys have almost always remained normal on follow-up DMSA renal scans. Surprisingly, reflux has been present in only 25%–50% of kidneys that developed new renal scarring. This is attributable in part to the fact that the majority of patients (63%–75%) with acute inflammatory changes on the initial DMSA renal scans did not have VUR. In one prospective study of 38 kidneys with initially abnormal DMSA scans, scarring developed in 6 of 15 (40%) kidneys with associated VUR and in 10 of 23 (42%) kidneys without demonstrable reflux.[65] Similar findings have been observed by others.[427] These observations provide convincing clinical evidence that renal parenchymal infection, rather than VUR, is the prerequisite for acquired (postnatal) renal scarring.

Despite these findings, the importance of VUR (particularly grade III or higher) as a risk factor for renal scarring should not be discounted. In two meta-analyses of all studies published until 2009, the aggregate risk for renal scarring following APN as reported in the worldwide literature was sought. Studies performing sequential DMSA renal scans to identify APN and subsequent renal scars in children presenting with febrile UTI showed that the presence of VUR yielded a two- to threefold greater

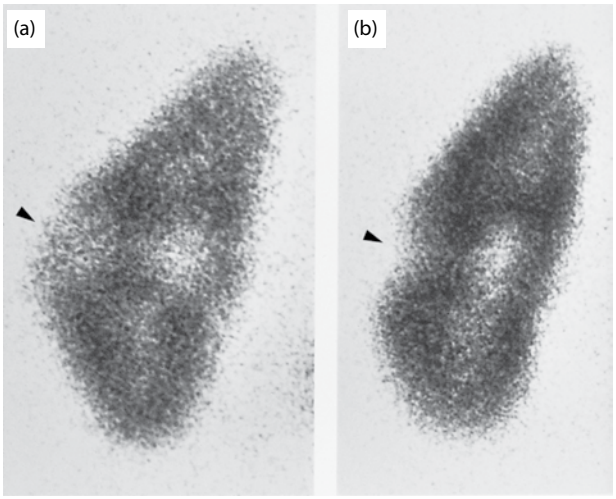

FIGURE 7.26 ^{99m}Tc DMSA renal scan in a 13-month-old girl with an acute febrile UTI. (a) Left posterior oblique view on the initial DMSA scan demonstrates acute pyelonephritis of the midzone of the left kidney evidenced by a photopenic lesion with preservation of the renal contour (arrowhead). (b) Follow-up DMSA renal scan reveals progression to renal scar in the exact same site characterized by contraction and loss of functioning renal cortex (arrowhead). (Reprinted from Rushton HG et al. *J Urol* 1992;147(5):1327–32. With permission.)

risk for renal scarring, and that children with grade III or higher VUR had a twofold greater risk of scarring than those with lower grades.[428,429] Although 62% of the kidneys with postpyelonephritic renal scarring in one study were drained by nonrefluxing ureters, renal scarring was still significantly more common in those kidneys with grade III or higher VUR than in kidneys with mild or no reflux.[427] Thus, the increased propensity for scarring in patients with higher grades of VUR is attributable in part to the increased risk of these kidneys for acute inflammatory damage at the time of the initial infection.[63,303,430] Coupled with this, reflux (pyelotubular backflow of urine from the pelvis into the collecting ducts) of infected urine or scarring of adjacent papillae may transform marginally competent, nonrefluxing papillae into papillae that do reflux, thereby predisposing the kidney to greater pyelonephritic damage.[63,408] Indeed, in one study that attempted to quantitate the area of acute pyelonephritic parenchymal damage, the presence of grade III or greater reflux was associated with a significantly greater frequency of kidneys demonstrating large defects (defined as >10% of the kidney demonstrating a DMSA uptake of <2 standard deviations of the control kidney) than kidneys with no VUR ($p < 0.02$).[430] Similarly, González et al. demonstrated that the risk of renal scarring affecting >25% of the kidney following DMSA-documented APN was 40% in patients with grades III and IV VUR compared with only 14% of those with grades I and II VUR and only 6% of those with no VUR.[431] Thus, when present, moderate or severe reflux (grade III or greater) remains the most significant host risk factor for APN and renal scarring.

Other risk factors for the development of renal scarring include associated bladder pathology, regardless of whether reflux is present. In one study, the frequency of new renal scarring was significantly higher in kidneys associated with overt bladder pathology than in those associated with normal bladders (86% vs. 32%, $p = 0.028$).[425] Yeung et al. evaluated 82 children with grades III or higher VUR. Those who had urodynamically proven abnormal bladder function were at significantly higher risk for development of breakthrough UTI and new renal scarring.[432] Urodynamic evaluation of children with neuropathic bladders associated with spina bifida has demonstrated that increased intravesical pressure may lead to upper tract deterioration, with or without VUR.[433] Animal studies have also shown an increased propensity for renal scarring when infection and reflux occur in the presence of bladder outlet obstruction.[408]

Two studies have also analyzed the association of various clinical and bacteriologic parameters with the development of new renal scarring.[425,427] In both, children who developed new renal scars were actually older at the time of APN, although the difference was statistically significant in only one.[426] An elevated WBC count at the time of the initial infection was not associated with renal scarring. When comparing those patients with and without new scarring, no significant differences were noted in race, gender, duration of fever, maximum temperature, or acute inflammatory signs (CRP or ESR) at the time of the acute pyelonephritic episode. *E. coli* was cultured from the urine of 88%–95% of the patients in both studies. Interestingly, new scarring occurred in 33%–41% of patients infected with *E. coli* compared with 100% of patients in both studies who were infected with other bacteria. In one study, no significant association was found between bacterial virulence factors (hemolysin, colicin, and P-fimbriae) and renal scarring, although colicin production was found almost twice as often in the bacteria isolated from patients with new renal scarring.[65] In a more recent report of 157 children evaluated with a DMSA renal scan 1 year following their first-time symptomatic UTI, children with high levels of CRP, high fever, and dilating VUR had an increased risk of renal scarring, up to 10 times higher than that of children with normal or slightly elevated CRP levels, no or mild fever, and no reflux.[350] Similarly, in a recent study evaluating serum PCT levels in patients with their first-time UTI, levels higher than 3.5 ng/mL were associated with an 18 times higher risk for renal scarring. Using a cutoff value of 2.0 ng/mL, an elevated PCT had a sensitivity of 97% and specificity of 66% for prediction of subsequent renal scarring.[258]

Imaging of Renal Scarring

In the past, the primary imaging modality for the detection of renal scarring was the intravenous pyelogram. However, limitations of IVP have actually hindered our understanding of the pathogenesis of renal scarring. Although relatively sensitive for the detection of renal scarring, IVP is not sensitive in the detection of APN.[308] Furthermore, pyelographic evidence of new renal scarring may take two or more years to develop after a documented UTI.[327,434] Consequently, this has forced investigators to speculate retrospectively about the etiology of renal scarring.

In contrast, DMSA renal cortical scintigraphy is capable of detecting the acute inflammatory changes of both

pyelonephritis and renal scarring. Several studies comparing the DMSA renal scan with IVP in the detection of renal scarring have demonstrated a greater sensitivity with isotope imaging, especially in younger children.[245,305,435–439] Merrick et al. compared the findings of IVP with those of DMSA scans in 79 children who had proven UTI and had been followed for a period of 1–4 years.[435] The sensitivity of IVP for the detection of renal scars was 80%, and the specificity was 92%, whereas cortical scintigraphy had a sensitivity of 92% and specificity of 98%. When both IVP and DMSA scintigraphy demonstrate scars, an excellent correlation on a site-by-site basis has been reported.[245,435–437,440] When compared with histology in an animal model, the sensitivity and specificity of the DMSA scan for the detection of renal scarring in 60 piglets with reflux and infected urine were 85% and 97%, respectively.[441] Studies that have compared ultrasonography with DMSA scintigraphy for the detection of renal scarring have consistently reported greater sensitivity with DMSA renal scans.[302,305,306] In one study, Yen and associates compared ultrasound, IVP, and both planar and SPECT DMSA renal scintigraphy in the evaluation of 130 children with UTI.[307] SPECT imaging of DMSA scans detected the highest number of defects, followed by planar imaging. Thus, DMSA renal cortical scintigraphy offers a superior opportunity to study the progression of renal damage or functional loss from the time of the initial insult until either complete healing or irreversible scarring develops.

Renal scars detected by DMSA scintigraphy appear as focal or generalized areas of diminished uptake of radioisotope associated with loss or contraction of functioning renal cortex. This may appear as thinning or flattening of the cortex in some kidneys, while in others, renal scars appear as classic discrete wedge-shaped parenchymal defects (Figure 7.27). In more severe cases, generalized damage may be associated with multifocal or diffusely scarred kidneys and reduced differential renal function. In contrast, defects associated with APN are more typically characterized by focal areas of diminished uptake but with preservation of the normal renal contour (Figure 7.26). Although it is often possible for an experienced observer to distinguish acute versus chronic lesions, it should be recognized that this differentiation may be less apparent in those kidneys with APN superimposed on preexistent renal scarring.

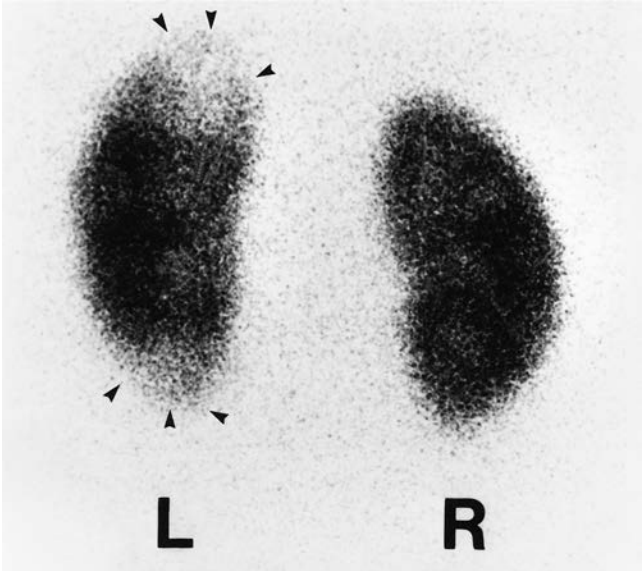

FIGURE 7.27 ^{99m}Tc DMSA renal scan demonstrates typical changes of acute pyelonephritis in the upper and lower poles of the left kidney. Diminished uptake of isotope is seen with an intact renal cortical outline without volume loss or contraction (arrowheads). (Reprinted from Cohen RA et al. *J Urol* 1990; 144:541–54. Sequelae of Renal Scarring

Hypertension

Renal scarring has been reported to be a common cause of hypertension in children and young adults.[440–443] The risk of hypertension in patients with renal scarring varies, based on length of follow-up and severity of scarring. In follow-up studies of children with renal scarring, approximately 6%–13% of children with scarring will develop hypertension.[23,231,446–448] In some cases, it may be associated with progressive renal insufficiency.[449] A report of an older cohort of 294 patients (mean age at presentation of 17.3 years) with reflux nephropathy noted that the risk of hypertension increased with age and length of follow-up.[450] Whereas 8.5% of these patients had hypertension at presentation, 38% became hypertensive later on (mean age 34.2 years). Hypertension was significantly more common in those with severe bilateral parenchymal scarring. Similarly, in another series, 13% (11/83) of children with renal scarring were hypertensive at initial evaluation and another 17% (14/83) developed hypertension over the subsequent 4–20 years.[451]

The development of hypertension is clearly related to the severity of renal scarring and is more often observed in patients with a history of recurrent episodes of pyelonephritis associated with moderate or severe VUR.[231,449] The actual risk for hypertension in children with milder degrees of scarring is unknown, but is undoubtedly much less. The etiology of hypertension associated with renal scarring is controversial. Some investigators report no evidence that the renin–angiotensin–aldosterone (RAS) system contributes to this, while others report that it does.[452–457] Despite these controversies, most would agree that the risk for hypertension in patients with severe renal scarring is significant, and long-term follow-up is mandatory, since hypertension may take 10–20 years to develop.

Renal Insufficiency

The actual risk of renal insufficiency secondary to post-pyelonephritic renal scarring is unknown. The annual incidence of new patients presenting with end stage renal disease (ESRD) associated with "reflux nephropathy" in Australia and New Zealand between 1985 and 1989 was 3.9 and 4.89 per million of the population, respectively.[458] Overall, this represented 7% of all new cases of ESRD commencing treatment during this time period, including 24% in the teenage group. In a more recent study of 102 patients with ESRD seen at a pediatric hospital over a 10-year period, only 3 had reflux nephropathy, including

1 patient with no history of UTI and another with a single, afebrile UTI.[459]

Studies have shown that the incidence of renal insufficiency in patients with postpyelonephritic renal scarring increases with age. The incidence of renal insufficiency in a report by Martinell et al. of 30 adults who were diagnosed with severe renal scarring as children was 10%.[23] Another study of an older cohort of 294 patients (mean age at presentation of 17.2 years) with reflux nephropathy found a 2% incidence of renal insufficiency (defined as GFR of <40–69 mL/min) at presentation, which increased to 24% at last follow-up (mean age 34.2 years). The more extensive the renal scarring, the higher the proportion with renal insufficiency.[449] Most patients (90%–100%) with reflux nephropathy and ESRD have focal segmental glomerulosclerosis, almost always associated with proteinuria.[460–463]

TREATMENT

The obvious goals of treatment of UTI are symptomatic relief and prevention of new or progressive renal damage, especially in infants and young children who are at greatest risk for renal scarring. Initial treatment, ideally, should be based on in vitro sensitivity studies. Frequently, such testing is not done or treatment is instituted before the results are available. Fortunately, because the common uropathogens are susceptible to multiple antibiotics and the response to antibiotics correlates best with urine levels that are usually more highly concentrated than serum levels, high cure rates have been reported in most therapeutic trials.[464]

Asymptomatic Bacteriuria

Treatment of true ABU does not appear to be necessary if the urinary tract is otherwise normal.[376,465,466] The risk for pyelonephritis in infants and young girls with untreated ABU is small, and many demonstrate spontaneous remission.[5,17] In a prospective follow-up of 50 infants with initial screening bacteriuria, 37 were followed for a minimum of 6 years.[467] Of the original 50, 2 infants developed pyelonephritis within 2 weeks of bacteriuria being diagnosed. In 45, bacteriuria was left untreated. Spontaneous clearance was observed in 36, while in 8 clearance followed treatment with antibiotics for respiratory infections. Recurrences of bacteriuria were observed in 10 of 50 children, of whom one had pyelonephritis. No child had more than one recurrence. Follow-up urography in 36 of 50 children after a median of 32 months showed no evidence of renal damage in any.

In contrast to infants with screening bacteriuria, treatment of school-aged girls with ABU is followed by high recurrence rates of up to 80%.[11] Most are caused by new strains, which may carry the risk of being more virulent.[468,469] In contrast, when ABU is left untreated, spontaneous changes of strain are uncommon.[470]

Several studies in the 1970s reported that nontreatment of ABU was associated with normal growth of kidneys without the development of new scars provided the urinary tract initially appeared normal radiographically.[14,283,285,286] In a 4-year follow-up by the Cardiff-Oxford Bacteriuria Study Group in children 5–12 years of age with untreated covert bacteriuria, new or progressive renal scarring did not occur unless VUR was present.[286] Similarly, the presence of ABU in the absence of VUR is not a risk factor for renal scarring in children with neuropathic bladders who perform clean intermittent catheterization.[378]

Hansson et al. retrospectively compared treatment with nontreatment of ABU in older girls (median age 8 years) with preexistent renal scarring.[471] Many also had mild grade I or II/V VUR. Of 21 girls who were given a short course of antibiotics, 17 acquired a new infection within a year, including 7 with pyelonephritic recurrences. Of 23 girls treated with antibiotic prophylaxis for 2–3 years, one-half developed breakthrough infections, and recurrences after completion of long-term prophylaxis were as common as after short-term treatment. Overall, in girls who received short- or long-term antibiotic treatment, 14 patients developed 21 episodes of APN during a total of 140 patient-years of observation. In contrast, ABU was left untreated in 29 girls for a total of 74 patient-years of observation. Only one patient developed APN.

Based on this information, it is reasonable that true ABU, particularly in older girls, be left untreated.[129,286] However, in the presence of VUR, the risks of nontreatment of ABU have not been clearly established, particularly in infants and younger children. It should also be recognized that bladder dysfunction is commonly found in girls with so-called ABU, including detrusor instability and incomplete emptying.[204] This explains in part the marked tendency for recurrent infection after treatment of ABU with antibiotics alone. Treatment of the underlying voiding dysfunction is key to the successful long-term management of these patients.

Uncomplicated Lower Urinary Tract Infection

Agents that have been used successfully for acute, uncomplicated lower urinary infections include sulfonamides, trimethoprim-sulfamethoxazole (TMP-SMX), nitrofurantoin, TMP, and oral cephalosporins (see the appendix). Unfortunately, ampicillin and amoxicillin are used commonly by primary healthcare physicians. High intestinal levels of these two antibiotics often result in rapid development of resistant enteric organisms, which then become the reinfecting bacteria. The emergence of resistant strains to ampicillin or amoxicillin has further limited its initial efficacy in treating urinary infections compared with other antibiotics.[472] Resistance rates to ampicillin or amoxicillin have been reported to be as high as 54% in children with their first documented symptomatic UTI.[473] This drawback of the synthetic penicillins has been diminished by the relatively recent combination of clavulinic acid with amoxicillin (Augmentin®). Clavulinic acid inhibits the bacterial β-lactamase enzymes, which render the β-lactamic antibiotics ineffective. This combination has proved effective in eradication of UTIs in children, even when in vitro susceptibility testing demonstrated resistance to amoxicillin alone.[474,475] However, ampicillin–clavulinic acid is associated with a high incidence of side effects, is expensive, and is no more effective than the

usual drugs. Increasing resistance to TMP-SMX has also been reported over the last decade.[368]

The fluoroquinolones have been shown to have a wide spectrum of activity that includes most gram-positive and gram-negative organisms, including *Pseudomonas aeruginosa* and *Proteus*.[476] However, concern regarding adverse arthropathic effects, based on animal studies showing cartilage toxicity, has prevented its approval for routine use in children.[477] However, the same experimental toxic effects have been reported with all quinolones, including nalidixic acid, which is licensed for use and has been used in children for decades.[478] A retrospective match-controlled study of nalidixic acid in 11 children treated for 10–600 days with follow-up examination 3–12 years later did not reveal any differences in arthropathic adverse effects compared with controls.[479] Furthermore, clinical evidence of cartilage toxicity has not been reported in more than 100 children with cystic fibrosis treated with varying courses of high-dose ciprofloxacin.[480] Currently, Cipro fluoroquinolone has received Food and Drug Administration (FDA) approval for the treatment of complicated UTIs in children.[481]

Several randomized controlled studies have been published reporting the efficacy of single-dose or short-course antimicrobial therapy for treatment of uncomplicated lower UTIs in children. The potential advantages of short-course therapy include decreased costs, improved compliance, decreased antibiotic-related side effects, and decreased effect on the fecal flora.

In 1988, Moffatt and associates reported a methodological analysis by four independent reviewers of 14 randomized controlled trials of short-course antimicrobial therapy for uncomplicated lower UTIs in children. Short-course therapy varied in these 14 studies. Conventional therapy ranged from 7 to 10 days. In two of the studies, short-course therapy was less effective.[482] One study compared single-dose with 10-day amoxicillin therapy and one compared 1-day with 10-day cefadroxil therapy.[483,484] The other 12 studies showed no difference in outcome. The authors concluded that there was still insufficient evidence to recommend short-course therapy for UTIs in children.

In a subsequent review article published by Khan, the findings in 12 of these reports were reevaluated by pooling the data on 320 infants and children.[485] He reported that single-dose therapy achieved an overall cure rate of 89% (63%–100%), defined as a negative follow-up culture at 1 week and the lack of a subsequent recurrence with the same organism. However, the response varied with the antimicrobial agents. Intramuscular aminoglycosides, used in 178 infants and children (56%), achieved the highest cure rate (96%), followed by TMP-SMX or a sulfa drug (90%). The cure rate of amoxicillin was significantly less (75%, $p < 0.01$). Another large clinical study investigated single-dose versus multidose antibiotic therapy in 132 children with a culture-documented "first-time" acute UTI. There was no difference in the bacteriologic cure rate for single-dose (93%) versus multidose regimens (96%), but recurrence rates at 10–12 days or 28–37 days after treatment were significantly higher in the single-dose group (20.5%) than in the 3-day (5.6%) and 7-day (8%) groups.[486]

Two other studies have compared relatively short 3-day with conventional 10-day courses of antibiotics for treatment of uncomplicated UTIs in children. In one prospective, randomized, open multicenter study of 264 girls, 1–15 years old, similar results were observed when short-course treatment with 3 days of either sulfamethizole or pivmecillinam was compared with 10 days of sulfamethizole.[487] Specifically, there was no difference in the number of girls with no or insignificant growth on urine cultures after treatment or in the recurrence-free interval after treatment among the three groups. In another study of 110 children, no difference in initial cure or subsequent relapse rates was found in children treated with 3-day therapy versus 10 days using either cotrimoxazole or nitrofurantoin.[488]

Based on the available data, it appears reasonable to treat acute lower uncomplicated infections in children with a relatively short 3-day course of antibiotics.

Pyelonephritis

The child with suspected pyelonephritis requires a greater degree of assurance of immediate therapeutic success, since the degree of scarring and renal damage resulting from an infection may be influenced by the rapidity of effective therapy.[40,326,410–413,489] Oral medication can be initiated in older children who are not septic or vomiting as long as good compliance is ensured. TMP-SMX can be anticipated to be effective in most cases. Cephalosporins are also a good choice for initial therapy in the febrile child who does not require parenteral therapy. Third-generation cephalosporins, such as cefixime, offer the advantage of once-daily dosing and have been shown to be as effective as twice-daily TMP-SMX.[490,491] Treatment can be changed to include less expensive agents when the antibiotic sensitivities become available.

There is controversy over the need for hospitalization and treatment with parenteral antibiotics versus outpatient therapy with oral drugs. However, in a prospective randomized clinical trial of 306 children 1–24 months old with febrile UTIs, outpatient treatment with oral third-generation cephalosporins was equally effective when compared with initial treatment with intravenous antibiotics. There was no significant difference in treatment success, duration of fever, or subsequent renal scarring on DMSA scans.[491] Not surprisingly, costs for treatment of children were significantly higher for those treated with intravenous antibiotics.

Clearly, there is a need for more controlled therapeutic trials for febrile UTI in children with old and new drugs in different dosages and for varying lengths of treatment. Ideally, these trials should categorize patients into different age groups, such as (1) neonates aged 0–28 days, (2) infants aged 1 month to <2 years, (3) older children of ≥2 years, and (4) adolescents.[492] Meanwhile, until such clinical trials are conducted, nontoxic children and infants of >2 months of age can be treated as outpatients as long as compliance is not an issue. It is also reasonable to initiate therapy with 1–2 days of a long-acting, third-generation cephalosporin, such as ceftriaxone, administered intramuscularly, followed by 10–14 days of oral antibiotics and prophylaxis until

evaluated. Ceftriaxone is active against most gram-negative uropathogens, and it achieves very high levels in both the urine and renal parenchyma following single daily doses.[493] This approach virtually ensures compliance and adequate antimicrobial coverage until the urine culture and sensitivity results are known. Alternatively, if compliance does not seem to be a problem, initial therapy with appropriate, broad-spectrum oral antibiotics may be as effective in the treatment of APN and in the prevention of irreversible renal damage.[491]

In contrast, the toxic child and infants of <2 months of age with suspected APN should be considered candidates for hospitalization and parenteral therapy. Typically, one of the newer third-generation cephalosporins may be used, but these do not provide comprehensive coverage of gram-positive organisms, including enterococcus. Parenteral antibiotic therapy should be continued for 5–7 days in neonates, although oral outpatient therapy to complete a full 10- to 14-day course can be substituted in patients of >2 months when afebrile for 24–48 hours. Follow-up specimens for urine culture should be obtained at the completion of therapy, and prophylaxis should be instituted until evaluation of the urinary tract is completed. In addition, circumcision may be considered in patients with higher grades of VUR and a history of febrile UTI based on the increased risk of UTI.

Dysfunctional Elimination

In addition to appropriate antimicrobial therapy, other factors must be taken into consideration in patient management. Voiding frequency and control of constipation are the two most common variables that are readily changeable and may be the most important in effecting changes in susceptibility to infection, particularly for children who are infrequent voiders. Establishing a voiding schedule in children may be extremely difficult and may provoke conflict in the parent–child relationship. The physician can interject his or her influence by explaining the treatment goal to the child and requesting that a regular voiding pattern be instituted and maintained. The child should be told that he or she will be reminded by his or her parents to void regularly, and that he or she should follow this request even if he or she does not feel the urge to void at that time. Multialarm wristwatches can be a useful and inexpensive reminder for older school-aged children.

The mainstay of treatment of children with recurrent UTIs and underlying bladder instability often involves the long-term use of anticholinergic medicine, primarily oxybutynin (Ditropan). Other anticholinergic and antispasmodic agents include hyoscyamine (Levsinex) and tolterodine (Detrol). Koff and Murtagh reported that after initial clearing of urinary infection, 31 of 58 (58%) children with recurrent UTIs and uninhibited bladder contractions who were treated with anticholinergics alone maintained sterile urine. The necessity for long-term antibiotic prophylaxis in these patients is then determined by the frequency of subsequent recurrences and/or the presence of VUR.[494] For children older than 6 years, the usual dosage of oxybutynin is 2.5–5 mg, given two to three times daily. A long-acting formulation, Ditropan XL, is available that only requires once-daily dosing. The usual dose for hyoscyamine in this age child is one 0.375 mg time capsule twice daily. Although not yet approved for children, tolterodine has been used successfully with doses of 1–2 mg twice daily. Reportedly, tolterodine has a more specific action on the bladder and is associated with fewer side effects. Comparative efficacy among these medications has not been established in children. Timed voiding should always be used in conjunction with anticholinergic therapy. Therapy directed toward associated constipation should always be initiated prior to starting treatment with intravenous anticholinergics.

In more difficult cases of voiding dysfunction with detrusor sphincter dyssynergia, pelvic floor relaxation biofeedback therapy has been used successfully in the treatment of recurrent UTIs.[495] In a report, 42 girls with recurrent UTIs and urodynamically confirmed dysfunctional voiding were treated with a multimodal approach involving pelvic floor relaxation biofeedback, a voiding and drinking schedule, anticholinergics in those with bladder instability, and antibiotic prophylaxis.[213] This combined therapeutic approach was effective in preventing recurrent UTIs in 35 girls (83%).

For constipation, an intensive therapeutic approach is often required. Increased intake of fiber and fluid and regular toilet habits must then be instituted. In refractory cases, regular use of a fiber-based laxative may be necessary. Initially, in severe cases, enemas given for several days may be necessary to disrupt a high fecal impaction and relax an overstretched colon. In most cases, the continuation of a bowel or bladder regimen is a long-term requirement, and failure to comply with this regimen generally results in recurrence of both constipation and UTI.[496] However, successful management can result in significant improvement in voiding dysfunction and a reduction in recurrent UTIs. A recent study of 234 constipated and encopretic children found that urinary infection was present in 11%, daytime urinary incontinence in 29%, and nocturnal incontinence in 34%.[213] During follow-up of at least 12 months after initiation of treatment for constipation, recurrent UTIs were effectively prevented in all patients who had no anatomic abnormality of the urinary tract. Daytime urinary incontinence resolved in 89% and nocturnal incontinence resolved in 63% of patients.

Urinary stasis for any other reason needs to be addressed if infection cannot be otherwise controlled with antibiotic prophylaxis. Wenske et al. have demonstrated that α-blockers are effective in decreasing postvoid residuals in children with primary bladder neck dysfunction.[497] Other causes of urinary stasis may include severe reflux with secondary poor bladder emptying (megacystis–megaureter syndrome), dilatation in the absence of obstruction, bladder diverticula, or residual ureteral stumps. Since otherwise unexplained urinary infection is so common, it is incumbent upon the physician to document the influence of any of these entities on infection prior to recommending surgical correction. For example, a specimen for culture may be obtained by needle aspiration of a dilated, nonobstructed upper collecting system to ascertain its involvement prior to surgical revision.

Renal Abscess

In the past, the majority of renal abscesses, a rare form of renal infection, were not thought to be the result of ascending infection. Historically, *Staphylococcus aureus* was the offending agent, resulting from hematogenous seeding from a peripheral cutaneous site of origin.[498,499] Diagnosis was often delayed in these patients because urine cultures are negative in most. With the advent of early recognition and effective therapy, the frequency of staphylococcal bacteremia and renal abscesses has decreased. More cases of gram-negative infections in the presence of VUR or other anatomic abnormalities of the urinary tract are now being seen.[500]

Most patients with a renal abscess present with high fever, leukocytosis, and an elevated ESR, often accompanied by flank pain. A variety of imaging techniques have been used to diagnose renal abscesses, including gallium-67 scintigraphy, sonography, and CT (Figure 7.28).[501–505] The classic treatment of renal abscess has been surgical drainage, in addition to appropriate antibiotic therapy. However, improved antibiotics and diagnostic techniques, together with the ability to obtain culture by percutaneous aspiration or drainage under ultrasonic control, have often obviated the necessity for surgical intervention. In seven patients reported by Schiff et al., 10 days of parenteral antibiotic treatment alone, followed by an additional 2 weeks of appropriate oral therapy, was successful.[506] However, in a review of the literature performed by Steele et al., 62% (16/23) of the children with renal abscesses ultimately required surgical intervention.[507] Unfortunately, in part due to the rarity of this type of infection, no controlled data exist that rigorously compare the resolution rate between children treated with antibiotics alone and those treated with antibiotics and drainage. Currently, many cases of renal abscess initially can be managed without intervention, with percutaneous drainage being reserved for persistent infection (Figure 7.29). Children who are immunocompromised by virtue of malnutrition or infection with the human immunodeficiency virus (HIV) are at particular risk for developing recurrent renal abscesses and abscesses containing unusual organisms (*Listeria monocytogenes*).[508,509] In these circumstances, more aggressive surgical or percutaneous intervention is often necessary early to eradicate the infection.

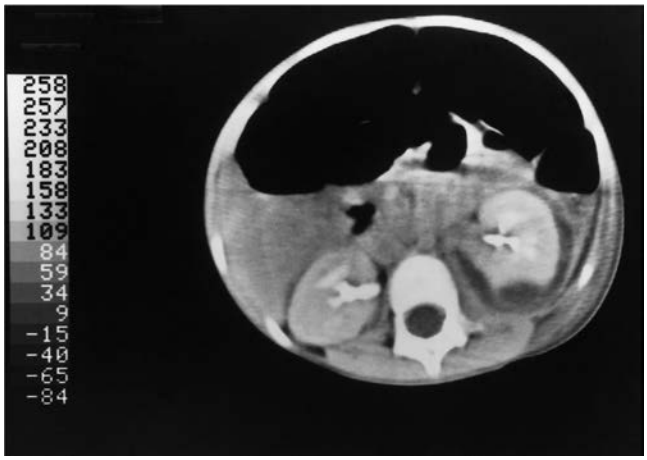

FIGURE 7.28 CT scan reveals a filling defect in upper pole of left kidney consistent with a renal abscess in a child with flank pain and fever. (Reprinted from Rushton HG. Genitourinary infections: nonspecific infections. In: Kelalis PP, King LR, Belman AB, eds. *Clinical Pediatric Urology*, 3rd edn. Philadelphia: WB Saunders, 1992. With permission.)

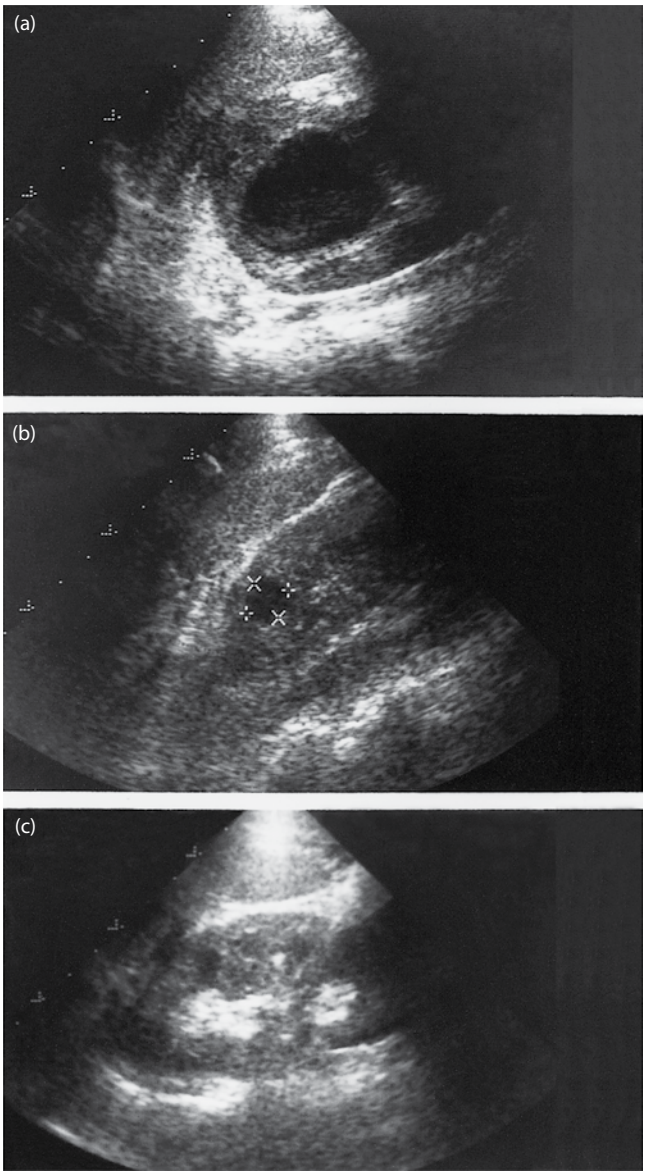

FIGURE 7.29 Sonogram in a 16-year-old girl who presented with fever and flank pain. (a) Sonolucent mass in the left upper pole consistent with a renal abscess. Needle aspiration under sonographic guidance yielded purulent material that grew *E. coli*. Following 2 weeks of parenteral and 4 weeks of oral antibiotic therapy, sonograms 7 weeks later (b) and 17 weeks later (c) show progressive resolution of abscess cavity. (Reprinted from Rushton HG. Genitourinary infections: nonspecific infections. In: Kelalis PP, King LR, Belman AB, eds. Clinical Pediatric Urology, 3rd edn. Philadelphia: WB Saunders, 1992. With permission.)

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is an atypical form of severe chronic renal parenchymal infection characterized by unilateral destruction of parenchyma and accumulation of lipid-laden macrophages (xanthoma cells) either surrounding abscess cavities or as discrete yellow nodules. More than 50 cases of xanthogranulomatous pyelonephritis have been reported in children.[496,510,511] The age of presentation has ranged from infancy to 16 years. Most patients present with nonspecific symptoms of chronic infection, including weight loss, recurrent fever, failure to thrive, pallor, and lethargy, although those with the focal form often appear healthy.[496,510] A palpable abdominal mass is present in approximately one-third of cases. Bacterial specimens for culture can be obtained from the urine or renal abscess in the majority of cases, with *Proteus* being the most common organism isolated.

Both diffuse and focal forms of the disease have been reported, with the focal form being more common in children than in adults.[510,512] The pathologic and radiologic differences between focal and diffuse xanthogranulomatous pyelonephritis have been described.[513] Radiologic evaluation in the diffuse form of the disease often reveals nonfunctioning of the entire kidney. Calcification or stones may be present, although this is less common in the focal form of the disease. Characteristic sonographic or CT appearances of xanthogranulomatous pyelonephritis also have been reported.[514] However, these features are nonspecific and often mimic neoplasia or other forms of chronic inflammatory renal parenchymal disease. Consequently, the correct diagnosis is seldom made preoperatively.[515] Nephrectomy is curative, although partial nephrectomy may be adequate in focal disease, assuming that the diagnosis can be established. No incidence of recurrence in the contralateral kidney has been reported.

Tuberculosis

Genitourinary tuberculosis (TB) is a form of secondary TB and is rare in children. Historically, it presents 1–5 years after initial infection.[516] It is more prevalent in non-Westernized populations, where TB is still endemic in many countries. It is important to be considered, however, in patients with immune deficiencies. Genitourinary TB most commonly presents in children with symptoms of lower UTI; however, mycobacterium is rarely identified on urine culture.[516]

Research in South Africa has investigated the renal effects of patients with coinfection of HIV and TB given the endemic presence of both diseases. The classical presentation of renal TB is kidney damage from obstruction or massive casseous destruction.[517] In this studied population, the presentation was granulomatous TB interstitial nephritis with renal function impairment and proteinuria. They concluded that TB can contribute to proteinuria and renal disease in children with HIV if they are not treated with antitubucular medications.[517]

The mainstay of genitourinary tuberculosis (GUTB) treatment is antimycobacterial chemotherapy, with surgical resection limited to patients with nonfunctioning kidney or recurrent infections.[518] Unroofing of renal abscess is no longer recommended when interventional radiology is present with the ability to drain the abscess percutaneously. Stricture disease and bladder fibrosis must also be managed appropriately. In children, this often means ureteral reconstruction for prevention of long-tern stricture complication and reoperations.[519] Isoniazid, pyrazinamide, ethambutol, and rifampicin in combination are the medications of choice. The time frame for treatment varies depending on the extent of disease. No randomized control trials have investigated the optimal duration of treatment for GUTB. Many recommendations include an "intense phase" with use of all four drugs for 2 months, followed by a "maintenance phase" of rifampicin and isoniazid for 4 months.[518] There is a rise in multi-drug-resistant TB associated with poorly managed pharmacotherapy, and many countries now utilize directly observed therapy to reduce the risk of drug resistance.

Treatment in Renal Failure

The dynamics of antibiotic detoxification and excretion are usually deranged in the child with renal failure. Antibacterial doses need to be adjusted in such patients to avoid adverse reactions. Certain drugs, those that are dependent on renal function for efficacy, are useless in these patients. The frequency of administration of those drugs that are effective in the face of renal failure, rather than their dosages, should be modified based on the degree of renal insufficiency.

Resistance

Negative selection imposed on the normal beneficial gut mircobiota by antibiotics may ultimately change the healthy state of the individual, resulting in an increased risk of opportunistic or recurrent infections.[520] More than 15 million women suffer from UTI annually in the United States, with estimated costs exceeding $2.5 billion.[521] UPEC is the causative agent in more than 85% of all UTIs, which are becoming more difficult to treat with increasing antimicrobial resistance to standard of care therapy and high recurrence rates leading to increased cost and a rise in multiresistant strains.[521] At this time, numerous groups are investigating possible molecular causes for increased bacterial resistance.[522–527] In the future, it may be possible to prevent and restrict resistance patterns in populations before they are endemic.

Antibiotic Prophylaxis

Long-term, continuous antibiotic prophylaxis has been recommended in children with a history of UTI and VUR (particularly under 5 years of age) and those with frequent symptomatic recurrences of UTI even in the absence of VUR. There are also children with prenatal hydronephrosis or a strong family history of VUR who are identified to have grades III–V VUR in whom antibiotic prophylaxis is recommended, particularly for those infants under 1 year of age.[201]

In the past, prophylaxis was usually continued in children with VUR until the reflux spontaneously resolved

or was surgically corrected. Some now advocate stopping prophylaxis in children older than 5 or 6 years of age who have mild or even moderate (grades I–III) VUR, particularly when there is no evidence of prior renal scarring.[528,529] If infection recurs during that time and reflux persists, correction should be considered for those with clinical or DMSA scan–documented pyelonephritis. Regardless of whether reflux is present, girls with a history of recurrent UTIs should be advised of the importance of surveillance urine cultures during pregnancy because they are at increased risk for pyelonephritis. In one review, a group of 41 women who had UTIs in childhood were followed through 65 pregnancies.[22] They were compared with age-matched controls. Of those with a history of childhood UTIs, 19 had renal scarring and 22 did not. The incidence of bacteriuria was higher in those with renal scarring (47%) than in those without renal scarring (27%), but both were significantly greater ($p < 0.001$ and <0.01, respectively) than in controls without a history of UTI (2%). This is true regardless of whether reflux is present.[21] Even those who undergo successful surgical correction of reflux during childhood may continue to be at increased risk for pyelonephritis during pregnancy.[530–532]

Children with recurrent pyelonephritis and those with frequent recurrent symptomatic lower UTIs (three in 6 months, four in a year) should also be considered for prophylaxis for a minimum of 6–12 months, even in the absence of VUR. Periodic urine specimens for culture should be obtained every 3–6 months to monitor the success of prophylaxis. Medication should then be reinstituted for an additional 12 months if infection recurs within 3 months of discontinuation. It is not necessary to discontinue treatment to obtain urine specimens for culture. When breakthrough infection occurs, the offending organism will be resistant to the current agent. Therefore, the culture media will not be sterilized by the excreted drugs.

Although prophylaxis effectively prevents infection, it may not reduce the recurrence rate of urinary infection after therapy has been discontinued. In one trial using TMP-SMX, all the children were treated for 2 weeks and then randomized to receive no treatment or 6 months of prophylaxis.[533] Although prophylaxis was highly effective in preventing infection, the rate of recurrent infection after stopping prophylaxis was virtually identical to that observed after 2 weeks of treatment. Similarly, Smellie et al. reported a high recurrence rate (42%) in children with a history of recurrent urinary infections following discontinuation of long-term antimicrobial prophylaxis.[534] Nevertheless, it is helpful to achieve an infection-free period in those children with a history of multiple, symptomatic urinary infections. During this period of time, aggressive efforts should be made to improve the voiding and bowel habit patterns in those children who have clinical and/or urodynamic evidence of dysfunctional voiding, a common finding in this difficult group of patients.

Antimicrobials with proven efficacy in the prevention of recurrent urinary infections include nitrofurantoin, TMP-SMX or TMP-sulfadiazine, and TMP alone.[466,534–536] In a double-blind study that compared prophylaxis with nitrofurantoin versus TMP alone in 130 children, nitrofurantoin demonstrated superior efficacy in those children with abnormal urography and/or reflux.[537] However, no differences were seen in children without urinary tract abnormalities. Nitrofurantoin did not alter the pattern of resistance of intestinal bacterial flora, while TMP significantly increased the percentage of TMP-resistant bacteria during prophylaxis. Side effects, primarily gastrointestinal, were more frequent in the nitrofurantoin group (37%) than in the TMP group (21%) ($p = 0.05$). The authors recommended nitrofurantoin as the first choice for prophylaxis in children with recurrent UTI and urinary tract abnormalities. Pure SMX is less effective, and synthetic penicillins are particularly poor prophylactic agents because of the frequent emergence of resistant organisms. Of note, these gastrointestinal side effects of nitrofurantoin can be significantly reduced by prescribing the macrocrystal formulation used in the capsular form of macrodantin. For young children who cannot swallow a capsule, these can be opened and the tasteless crystals mixed with soft food, yogurt, or ice cream.

Prophylactic doses are generally less than those used to treat acute infection. Smellie et al. effectively used 10 mg SMX plus 2 mg/kg/day TMP or 1–2 mg/kg/day nitrofurantoin in one to two doses.[534,538] Our practice is to administer one-third to one-half of the therapeutic dose once daily. Alternatively, intermittent prophylaxis with low-dose TMP-SMX every other day has also been reported to be effective in both children with VUR and preadolescent girls with recurrent infection.[538–540] In difficult cases of children who develop breakthrough UTIs on single-drug antimicrobial prophylaxis, double prophylaxis with nitrofurantoin and TMP-SMX has been shown to be effective in reducing recurrences.[541] In one study of 31 girls with recurrent breakthrough infections on single-drug therapy, 68% had VUR, 49% had voiding dysfunction, and 26% had both.[542] When treated with double-drug prophylaxis, the rate of infection was reduced from 17.4 UTIs/100 patient months to 3.6 UTIs/100 patient months ($p < 0.001$). These patients were also treated with anticholinergics and frequent timed voiding.

Earlier recommendations were based in part on the concern for long-term morbidity associated with renal scarring secondary to recurrent UTIs and VUR.

However, evidence shows that only a small subgroup of children are at risk for significant morbidity. Furthermore, not all small kidneys are the result of scarring secondary to UTI and VUR, as some are congenitally dysplastic kidneys that occur in association with high-grade VUR.[543] It has also been noted that despite more aggressive identification and treatment of VUR over the last four decades, the incidence of ESRD associated with reflux nephropathy has not decreased based on transplant registry data.[544] Consequently, the UK National Institute for Health and Care Excellence (NICE) guidelines in 2007 and the American Academy of Pediatrics (AAP) guidelines in 2011 have recommended a more selective approach to the evaluation and treatment of UTI and VUR with antibiotic prophylaxis.

Recent studies that have assessed the efficacy of long-term low-dose antibiotic prophylaxis have yielded conflicting results. A multicenter, randomized controlled noninferiority trial of children under 7 years of age with first febrile UTI were used to compare no prophylaxis with

prophylaxis for 12 months with end points of recurrent febrile UTI. Intention to treat showed no significant differences in the primary outcome between no prophylaxis and prophylaxis for febrile UTI or in a secondary outcome examining renal scarring on a 12-month DMSA scan.[545] Similar findings have been reported in other recent studies, which mostly included patients with mild to moderate VUR.[266,331,543,546] However, these trials were limited by sample sizes from 100 to 218 and therefore could not evaluate the effect of reflux severity. A subsequent meta-analysis of randomized control trials concluded that evidence is lacking that prophylactic antibiotics reduce the incidence of recurrent childhood UTI.[547] Similarly, a Cochrane review that compiled data from 20 randomized trials, including 2324 children, noted significant variation in methodologic quality, which made it difficult to form firm conclusions. However, when averaged across the studies, antibiotic prophylaxis did not appear to result in a significant reduction in febrile UTIs in children with VUR.[548]

In contrast, Craig et al. showed in the PRIVENT study that long-term low-dose TMP-SMX was associated with a decreased number of UTIs in predisposed children.[547,549] Children under the age of 18 were randomized to prophylaxis with TMP-SMX or placebo. Forty-two percent had VUR (at least grade III in 53% of these patients), and 71% were entered after their first known UTI. The investigators found a 6% absolute reduction in those receiving antibiotic prophylaxis, with 19% in the placebo group and 13% in the prophylaxis group developing a recurrent UTI. In the Swedish Reflux Trial, 203 children with grades III and IV VUR and a history of UTI were randomized to antibiotic prophylaxis, surveillance, or endoscopic treatment. Antibiotic prophylaxis resulted in a significant reduction of recurrent febrile UTIs and new renal scarring when compared with placebo. Currently, the results of the NIH RIVUR Study with 600 patients with grades I–IV VUR randomized to antibiotic prophylaxis versus placebo are awaited.

It appears to be increasingly clear that antibiotic prophylaxis is probably not beneficial in low-risk populations that are not predisposed to recurrent UTIs. In contrast, antibiotic prophylaxis does confer a therapeutic advantage in higher-risk patients, that is, those with higher grades of VUR, renal scarring, dysfunctional elimination, and/or a history of recurrent UTIs.

Inoculation with Benign Bacteria

Mutaflor® is a commensal *E. coli* strain that eradicates pathogenic bacteria from the gastrointestinal tract. It alters the intestinal biome, and theoretically, it could be used as an alternative to probiotics in the prevention of recurrent UTIs. In an experimental study, Storm et al. used in vitro assays to analyze the effectiveness of Nissle 1917 for eradicating collections of 43 bacterial pediatric uropathogens. Nissle 1917 adversely affected the growth of 34 of 43 isolates. It inhibited the growth of 21 isolates and overgrew 13 isolates, with the breakdown of 40% *Pseudomonas*; 50% *E. coli*, *Enterococcus*, and *Staphylococcus*; 100% *Klebsiella* and *Enterobacter*; and none for *Citrobacter* and *Serratia*. Since it outcompeted or inhibited most bacterial isolates in the studied library, more research is needed to determine if inoculation with Nissle 1917 could actually help prevent recurrent UTIs.[550]

APPENDIX: ANTIBACTERIAL AGENTS

Sulfonamides

Sulfonamides act by competitively blocking the conversion of para-aminobenzoic acid to folic acid.[551] About 75% of the oral dose is absorbed. Free sulfonamide is excreted into urine by filtration and tubular secretion. Although high tissue levels are not achieved, excellent urine levels result. Sulfonamides are most effective against *E. coli*, but also may be effective against other gram-negative and gram-positive organisms.

Sulfonamides are well tolerated by children, are inexpensive, and produce few side effects. They affect the gastrointestinal flora when used for long-term prophylaxis but are effective agents for short-term acute therapy of uncomplicated infections. They displace protein-bound bilirubin and hence in the neonate have the potential to interfere with bilirubin excretion and cause jaundice. Once the infant has passed through the period of "physiologic jaundice," these agents can be utilized safely. Some patients are allergic to sulfa, but fortunately, most reactions are of a minor cutaneous nature, such as urticaria. There have been some problems with major hypersensitivity reactions, such as the Stevens–Johnson syndrome, but these are rare. The most widely used agent is sulfisoxazole, employed in a dose of 120–150 mg/kg/day, given acutely in four to six divided doses orally.[552]

Trimethoprim-Sulfamethoxazole

The TMP-SMX combination is useful both in the management of simple cystitis and for long-term antibacterial prophylaxis. This combination has a diminished effect on bowel flora and offers the advantage of TMP entering vaginal secretions in the adult female.[553] This latter characteristic appears to be of particular utility in its effectiveness as a prophylactic agent. In addition, trimethoprim has also been shown in vitro to induce phase variation of fimbriated *E. coli* to a nonfimbriated state.[554] This and the high concentration in vaginal secretions work to prevent vaginal and periurethral colonization with organisms that could potentially cause UTI. TMP interferes with dihydrofolic acid reductase, and sulfa blocks the conversion of para-aminobenzoic acid to dihydrofolic acid. The combination is effective against many gram-negative as well as gram-positive organisms. It is well absorbed, attains high levels in both serum and urine, and is well tolerated by children. Neutropenia and thrombocytopenia are not uncommon with its use. However, the significance of these changes is unknown.[555]

The combination is available as a suspension containing 40 mg of TMP and 200 mg of SMX per 5 mL. The dose employed in children over 2 months of age is TMP, 6–12 mg/kg/day, and SMX, 30–60 mg/kg/day, in two divided doses.[552]

Nitrofurantoin

Nitrofurantoin is quite useful in the treatment of simple cystitis and is also a very effective agent for long-term low-dose prophylaxis. It is thought to interfere with the early stages of the bacterial Krebs cycle.[556] It is well absorbed from the gastrointestinal tract and has minimal effect on bowel flora. Hence, the resistance rate of UPEC has remained low. Tissue levels are low because it is excreted almost entirely in the urine by glomerular filtration. Urinary levels tend to be quite high. Urinary alkalization increases urine levels, whereas acidification increases tissue levels. It works well against most *E. coli* and enterococci but is not particularly effective against *Klebsiella*, *Proteus*, or *Pseudomonas*.

Nausea and vomiting are frequent troublesome side effects in children; however, these can be minimized by administering the agent immediately following a meal or by utilizing nitrofurantoin macrocrystals supplied in capsule form. For the small child, the contents of the capsule can be emptied and administered in potatoes or applesauce.

In neonates, nitrofurantoin has the potential to cause a hemolytic anemia because of glutathione instability. Consequently, it should not be used in this age group. Additionally, the drug is ineffective in patients with significant renal impairment. Other side effects are rare but do include peripheral neuropathy and pulmonary infiltrates. The usual dose in children older than 3 months of age is 5–7 mg/kg/day given orally in three to four divided doses.[552]

Penicillins

Historically, the penicillins as a class were probably the most widely used antibiotics. All act by blocking mucopeptide synthesis in the cell walls so that the bacterium is unprotected from its high internal osmotic pressure.[557] This effect occurs only in growing cells. However, use of the penicillins in the treatment of UTIs is decreasing due to the emergence of resistant strains of uropathogenic bacteria.

Penicillin G

Extremely high urine levels can be achieved with penicillin G in patients with normal renal function, and under those circumstances, this drug may be very effective against both *E. coli* and *Proteus*. Its major toxic effect is allergy manifested by rash or anaphylaxis.

Ampicillin

Ampicillin is the most widely used penicillin in the treatment of UTIs. It is not well absorbed from the gastrointestinal tract; therefore, high fecal levels do occur and diarrhea is common. High serum and urine concentrations are achievable. This agent should not be administered to patients with a known history of penicillin allergy. The usual dose is 50–100 mg/kg/day given every 6 hours. It can be administered either orally or intravenously.[552]

Amoxicillin

Amoxicillin is a derivative of ampicillin that is absorbed more readily and therefore produces less diarrhea. It is administered orally in a dose of 20–40 mg/kg/day every 6–8 hours.[552]

Carbenicillin

Carbenicillin is an agent that may be useful in the treatment of *Pseudomonas* and indole-positive *Proteus*; however, its usefulness is often diminished by the emergence of resistant strains. It is available as tablets and as a parenteral solution. When it is used parenterally for UTI in children, the usual dose is 50–200 mg/kg/day given every 4 hours; for severe infections, the dose can be increased to 400–500 mg/kg/day.[558] The oral form is not predictably effective in children.

Ticarcillin

Ticarcillin is available for parenteral therapy only. Like carbenicillin, it is active against *Pseudomonas* and indole-positive *Proteus*, which may be resistant to other drugs. It is often used with an aminoglycoside for a synergistic effect. This combination may also delay the emergence of resistant strains. Sodium overload is less likely to occur with ticarcillin than with carbenicillin. The usual dose in children for treatment of UTI is 50–100 mg/kg/day given every 4–6 hours. In life-threatening infections, the dose can be increased to 200–300 mg/kg/day.[558]

Piperacillin

Piperacillin has essentially the same antimicrobial spectrum as carbenicillin and ticarcillin, but is more effective on a weight basis. Piperacillin may have some advantage in allowing lower doses and therefore less sodium load than carbenicillin and ticarcillin. The dosage in children is 50 mg/kg/day given every 4–6 hours.[558]

Cephalosporins

Cephalosporins are usually effective against most of the gram-negative and many of the gram-positive pathogens. Excretion is by both glomerular filtration and tubular secretion. Although there can be some cross-reactivity in patients who are allergic to penicillin, in general these agents can be cautiously administered to patients with penicillin allergy.

Oral Drugs

Oral cephalexin, a first-generation cephalosporin, is well absorbed from the gastrointestinal tract and can be given in a dose of 25–50 mg/kg/day every 6 hours.[552] Cefaclor, a second-generation oral cephalosporin, is somewhat more active against gram-negative bacteria but is more expensive than cephalexin. The dosage is 20–40 mg/kg/day given every 8 hours.[552] Other oral cephalosporins include cephradine (first generation) and cefadroxil (second generation). A new third-generation cephalosporin for oral administration, cefixime, is available. In addition to

broader coverage of gram-negative organisms, an advantage of cefixime is a prolonged half-life, allowing for once or twice daily dosage. The recommended dose for children is 8 mg/kg/day in one or two divided doses.[559]

Parenteral Drugs

Numerous cephalosporins are available for parenteral use. The first-generation cephalosporins (cephalothin, cefazolin, cepharadine, and cephapirin) are useful agents for urinary infections caused by most strains of *E. coli*, *Klebsiella*, and *Proteus*, but not *Pseudomonas*. As with all cephalosporins, they are inactive against enterococci. The second-generation parenteral cephalosporins (cefamandole and cefoxitin) are more active than the first-generation agents against many enteric gram-negative bacteria, but not *Pseudomonas*. Cefoxitin is the most active cephalosporin against anaerobes, including *Bacteroides fragilis*. There are a number of new third-generation cephalosporins (cefoperazone, cefotaxime, ceftazidime, and ceftriaxone). These drugs have been developed because of their relatively greater activity against gram-negative bacteria. Although most retain some activity against gram-positive bacteria, they are much less active than first-generation cephalosporins for staphylococci or other gram-positive bacteria. Ceftriaxone has a longer half-life, allowing for once or twice daily dosage. It is also more active than cefoperazone against most gram-negative bacteria.

Other Cephalosporins

There are so many new cephalosporins that it is difficult to choose among them: cefoxitin, cefotetin, cefmetazole, and flomoxef. Cephamycins are β-lactam antibiotics that are similar to cephalosporins and are classified as second-generation cephalosporins. It is recommended that the physician become familiar with the use of one oral and one parenteral drug in each generation. Dosage in children varies with each cephalosporin.

Aminoglycosides

The aminoglycosides are well tolerated by children and are of special utility in the treatment of complicated gram-negative UTI. They interfere with protein synthesis by binding proteins of the bacterial ribosomes.

Gentamicin

Gentamicin is probably the most widely used of the aminoglycosides in children and is especially effective against *Pseudomonas*. The usual pediatric dose is 5–7.5 mg/kg/day parenterally in two divided doses, depending on age.[552] It achieves high tissue concentration and can be ototoxic, particularly to the vestibular cells. Nephrotoxicity also occurs in a small percentage of patients and should be watched for by checking serum creatinine periodically during the course of therapy. Nephrotoxicity occurs particularly frequently when gentamicin is given in combination with cephalosporins. Both ototoxicity and nephrotoxicity are usually transient.

Tobramycin

Tobramycin has the advantage of particular efficacy against *Pseudomonas*. It is said to be less nephrotoxic than gentamicin.[560] The dosage is 4–7.5 mg/kg/day given every 8–12 hours, depending on age.[552]

Amikacin

Amikacin was developed to improve activity against emerging resistant strains of *Pseudomonas*. As with other aminoglycosides, it is potentially both nephrotoxic and ototoxic. The dosage is 15–22.5 mg/kg/day given every 8 to 12 hours, depending on age.[552]

Tetracyclines

Tetracyclines should not be used in children under 8 years of age because they stain the permanent teeth. The need for tetracycline is extremely unusual in modern-day pediatrics.

Clavulanic Acid

Clavulanic acid is a β-lactam structurally related to the penicillins, but it has little antimicrobial activity alone. It inactivates a wide variety of β-lactamases by blocking the active sites of these enzymes. Clavulanic acid is particularly active against the clinically important plasmid-mediated β-lactamases frequently responsible for transferred drug resistance to penicillins and cephalosporins.[561] Clavulanic acid is commercially available in combination with amoxicillin as Augmentin. The recommended pediatric dose of Augmentin is based on patient weight less than 40 kg. For severe infections, 40 mg/kg/day is given every 12 hours. For less severe infections, 20 mg/kg/day is given every 12 hours. For neonates and infants less than 3 months of age, the recommended dosing is 30 mg/kg/day based on renal excretion. For patients weighing greater than 40 kg, it is recommended that adult dosing guidelines be followed.

Carbapenems

Carbapenems are a β-lactam antibiotic that are effective against gram-positive, gram-negative, and anaerobic bacteria with the exception of intracellular bacteria. These antibiotics readily penetrate the bacterial cell walls to inhibit cell wall synthesis. The structure of these drugs provides stability that enables them to be extremely resistant to most β-lactamases.[562] Some gram-negative bacteria with decreased porin production have decreased cell wall permeability, leading to increasing resistance. Increasing resistance patterns have been seen particularly in extended-spectrum β-lactamase (ESBL) *E. coli* that will likely have a serious impact on our ability to treat multidrug-resistant UTIs.[563] This class of medications includes imepenem, meropenem, ertapenem, and doripenem. The recommended dosing for meropenem is 20 mg/kg, up to maximum of 1 g every 8 hours. Ertapenem for children over 13 years of age is 1 g daily, but for children 3 months to 12 years, the recommended dosing is 15 mg/kg every 12 hours, not to exceed a maximum dose of 1 g daily.

Quinolones

Flouroquinolones are bactericidal agents that work by inhibiting the essential bacterial enzyme DNA gyrase, which is essential for DNA replication in bacterial cells.[564] Fluoroquinolones have been associated with arthropathy and histopathologic changes in weight-bearing joints of juvenile animals. For this reason, ciprofloxacin has been avoided in pediatric populations. Recently, the AAP has approved the use of fluoroquinolones to treat certain infections. One specific approved use of ciprofloxacin is in childen older than 1 year of age with complicated UTIs and pyelonephritis.[481] This medication is reserved for multi-drug-resistant populations of patients and/or patients in which oral ciprofloxacin enables the patients to avoid long-term intravenous therapy. For complicated UTIs for patients age 1–17, the recommended dosing is 10–20 mg/kg orally every 12 hours or 6–10 mg/kg intravenously every 8 hours. The maximum recommended doses are 400 mg/dose intravenously and 750 mg/dose orally.

CHAPTER
8

Fungal, Parasitic, and Other Inflammatory Diseases of the Genitourinary Tract

Aviva Weinberg and William A. Kennedy II

FUNGAL INFECTIONS OF THE URINARY TRACT

Candidiasis

Pediatric fungal UTIs have increased in prevalence with the rising number of preterm infants receiving aggressive neonatal intensive care unit (NICU) management and the increasing numbers of immunocompromised pediatric patients surviving malignancies, HIV, and solid organ and bone marrow transplantation. In preterm infants and children, predisposing risk factors may include broad-spectrum antimicrobial therapy; intravenous, urinary, or umbilical artery catheterization; long-term parenteral nutrition; low birth weight; fungal colonization; congenital conditions; and immunocompromised status. The incidence of invasive candidiasis in the NICU increases with decreasing birth weight, with rates as high as 10% reported in extremely low-birthweight (ELBW) (<1000 g) infants.[1] The spectrum of *Candida* infection ranges from catheter-associated candidemia to single-organ or disseminated infection. The urinary tract may act as a primary route of entry in the form of candiduria or as a site of disseminated infection, as in renal candidiasis manifested as renal fungal balls or renal parenchymal infiltration.

Candida species are the leading isolate associated with fungal UTIs in the pediatric population, with *Candida albicans* as the most common of these opportunistic mycoses, accounting for more than 50% of cases. *Candida parapsolosis* has become the second most common species after *C. albicans*, due to the extensive use of indwelling catheters. *C. albicans* is a yeast that belongs in the commensal flora of the mouth, intestinal tract, vagina, and skin. *Candida* is the most common opportunistic mycosis. The same clinic risk factors that predispose to candidemia also heighten the risk of candiduria. Risk factors include ELBW infants, extreme prematurity, central venous catheters, parenteral nutrition, indwelling Foley catheters, steroid administration, the use of H2-receptor antagonists, the use of broad-spectrum antibiotics, and the presence of congenital urinary tract anomalies.[2] Systemic candidiasis is found in 35%–52% of cases of neonatal candidal UTI.[3] The frequent association of candiduria and candidemia supports the role of systemic antifungal treatment.

Pediatric patients with candidal UTIs can present with a range of symptoms, from fever, lethargy, feeding intolerance, respiratory distress, and abdominal distention to frank urosepsis in cases of renal candidiasis.[4] In patients with localized *Candida* cystitis, symptoms often consist of urinary frequency, urgency, and dysuria. Common laboratory features include a leukocytosis with "left shift" and thrombocytopenia. Renal candidiasis may present with either a nonoliguric acute renal failure, with a rising serum creatinine in the face of normal urine output, or an anuric renal failure due to urinary obstruction caused by ureteral fungus balls.[5] Renal pelvis fungus balls have been found at a rate as high as 35% in infants with candiduria who underwent renal ultrasound imaging.[6]

Diagnosis of candiduria is made by urine culture. In the neonate, appropriate methods of obtaining urine cultures include sterile urethral catheterization or suprapubic aspiration. While suprapubic aspirate has generally been considered the "gold standard," it is not routinely performed in the NICU, but rather sterile urethral catheterization is considered the most efficient collection method. A suprapubic aspirate with $>10^3$ or $>10^4$ CFU/mL via urethral catheterization has been previously defined as indicative of candidal UTIs. Urine specimens taken from indwelling catheters may have colony counts as high as 10^5/mL with no relationship to upper tract candidal infection.

Renal candidal involvement may be secondary to systemic infection, during the course of candidal cystitis, or may be involved primarily without other organ involvement. Renal ultrasound imaging has been the imaging modality of choice in the diagnosis of renal candidiasis because of its portability, noninvasiveness, and lack of radiation exposure. Typical ultrasonographic features of renal candidiasis consist of an enlarged and echogenic kidney with a dilated pelvicalyceal system filled with fungus balls (Figures 8.1 and 8.2).[7] Fungus balls are commonly described as a nonshadowing echogenic focus.[8] While this finding is nonspecific, and may represent blood clot, fibrinous deposits, or nephrocalcinosis, it is highly suggestive of renal candidiasis, when taken within the clinical context of a positive blood or urine culture for *Candida* species. Currently, there is limited experience with computed tomography (CT) and MRI of renal candidiasis. The CT appearance of fungus balls

FIGURE 8.1 Candidal fungus balls in a 4-week-old boy. (From Mercado-Deane M. et al. *Radiographics* 2002;22:1429–38.)

is that of collecting system soft tissue masses without mass effect (Figure 8.3).[9] MRI has been reported to be superior to CT delineation of renal candidiasis, with T2-weighted and short tau inversion recovery (STIR) sequences the best for distinguishing between fungal infiltrates and urine. However, ultimately the greater portability and the ease of sequential imaging have made ultrasound the imaging method of choice to date. At present, renal ultrasound imaging is recommended in the setting of a positive urine culture for *Candida*, persistent candidemia, or cases of systemic candidiasis associated with a rising serum creatinine. Some authors have recommended serial ultrasound imaging, as a normal renal ultrasound at the onset of candiduria cannot exclude the later development of renal involvement. In a study by Bryant et al., more than half of candiduric infants were

FIGURE 8.2 Candidal bezoar and renal dilation. (From Mercado-Deane M et al. *Radiographics* 2002;22:1429–38.)

FIGURE 8.3 Abdominal CT shows multiple low-density lesions in both kidneys consistent with primary renal candidiasis. (From Li W.-Y et al. *Kidney Int* 2007;72:382.)

found to have renal infiltration as late as 8–39 days after an initially normal imaging study.[3]

The treatment of candiduria is dependent on the extent of infection. Candiduria that occurs in otherwise healthy children after long-term broad-spectrum antibiotics should clear spontaneously after the antibiotics are stopped. A wide range of therapies have been reported, including urinary tract irrigation with antifungal agents, systemic antifungal therapy, nephrostomy decompression, nephrectomy, and drainage of perinephric abscesses. Surgical management has been reserved for cases of urinary obstruction and renal abscess formation, with the vast majority of cases effectively managed medically. Symptomatic infections limited to the lower urinary tract may be eradicated by bladder instillations and irrigations with a solution of amphotericin B (5–15 mg in 100 mL of sterile water, allowed to dwell for 60–120 minutes, three or four times daily).[10] Upper tract candidal infection may be treated with nephrostomy tube irrigation with amphotericin solution or oral 5-flucytosine. It should be noted, however, that 5-flucytosine should be avoided in children with azotemia or bone marrow suppression. The American Academy of Pediatrics Committee on Infectious Diseases has recommended amphotericin B as the drug of choice for systemic candidiasis, without any mention of candiduria treatment guidelines.[9] Treatment of candiduria with nonobstructive renal candidiasis has thus been extrapolated from these recommendations. Current treatment protocols consist of amphotericin B at 1 mg/kg/day, with or without 5-flucytosine, for 7–14 days after blood and/or urine cultures become negative. Unfortunately, no randomized trials have been performed outlining the appropriate duration of antifungal therapy. The persistence of renal ultrasound abnormalities despite prolonged systemic antifungals and sterile urine cultures makes recommendations for treatment duration even more problematic. Amphotericin B is nephrotoxic and must be meticulously titrated to obtain appropriate serum levels, and monitoring of serum creatinine is necessary, with prolongation of the dosing interval in the event of

a rising serum creatinine. Additional toxic side effects include fever, nausea, vomiting, malaise, and renal failure. Liposomal formulations are not recommended due to their poor renal penetration.

Other antifungal agents include fluconazole, caspofungin, micafungin, and anidulafungin. Unfortunately, clinical data on these other antifungals are limited in the neonate and pediatric population. Fluconazole, which has been associated with less nephrotoxicity than amphotericin B, is used with caution due to its lower efficacy against non–*C. albicans* species.

Obstructive uropathy caused by renal candidiasis is typically treated surgically. Obstructing fungus balls have been removed by pyelotomy, percutaneous abscess drainage, insertion of nephrostomy tubes with direct amphotericin irrigation, or even nephrectomy in severe cases. Rapid diagnosis and systemic antifungal therapy have become the standard of care, making the need for surgical intervention quite rare. However, whenever obstructive nephropathy is present, a pediatric urologist should be promptly consulted to evaluate the necessity of surgical intercession.

Aspergillosis

Aspergillosis refers to the spectrum of diseases caused by the mycelial fungi of the genus *Aspergillus*. Currently, *Aspergillus fumigatus* and *Aspergillus niger* are the most common strains. Aspergillosis is the second most common opportunistic fungal infection in the immunocompromised pediatric patient population.[11] *Aspergillus* is a widely disseminated saprophyte in soil, and has been isolated from moist environments, such as air-conditioning systems.[12] Outbreaks of invasive disease usually occur among immunocompromised children as a result of exposure to aerosolized spores. Inhalation of the airborne spores allows entry of the pathogen into the body, at which point in the setting of immunocompromise, the organism is widely disseminated through hematogenous spread. Other potential portals of entry include open operative wounds or indwelling foreign bodies, such as intravenous or urinary catheters. Invasive forms of aspergillosis have increased as a reflection of the improved survival of immunocompromised children and advances in the treatment of children with organ transplantation and hematopoetic stem cell transplant (HSCT). The single greatest risk factor for invasive *Aspergillus* in these settings is neutropenia.

Invasive aspergillosis has been fairly well characterized in the literature, but very few studies describe the clinical features, diagnosis, and ideal treatment for pediatric genitourinary involvement. Rare case reports document cases of *Aspergillus* fungus balls in the setting of bladder exstrophy and HSCT.[12] Microscopic hematuria and pyuria are commonly present in patients with aspergillosis. The fungi may be identified as branched septate hyphae on potassium hydroxide preparations of infected urine. Results of urine culture are often inconclusive, and multiple cultures may be necessary to make a diagnosis. Recent advances in invasive aspergillosis diagnostics include the galactomannan (GM) assay, a major cell wall constituent that can be assayed in serum; a beta-D glucan serum assay; and *Aspergillus* polymerase chain reaction (PCR) testing. Unfortunately, there are limited data as of yet in the pediatric population for these serological diagnostic tests. As with candidal urinary involvement, renal ultrasonography remains the most effective method for the detection of fungus balls.[13]

FIGURE 8.4 Renal aspergillosis in the setting of Acute Lymphoblastic Leukemia (ALL). Notable findings include poorly enhancing, low-attenuation, mass-like renal parenchymal lesion extending to the renal sinus. Aspergillosis may also cause vascular occlusion and multiple renal infarcts. The parenchymal lesions may be difficult to radiographically distinguish from primary renal tumors. (From Rha SE et al. *Radiographics* 2004;24:S117–31.)

Obstructive uropathy resulting from an aspergilloma in the renal pelvis or the bladder is a matter of rare case reports. Renal aspergillosis is typically characterized by focal microabscess formation, hyperechogenic material in the renal pelvis, and occasionally papillary necrosis (Figure 8.4).[14]

Treatment of invasive aspergillosis with renal involvement remains a combination of systemic antifungal agents, placement of percutaneous nephrostomy catheters, and local irrigation.[16] High-dose amphotericin B and voriconazole remain the leading options in systemic antifungal treatment. Currently, voriconazole, due to its decreased risk of nephrotoxicity, is considered the superior agent. Finally, percutaneous or open surgical removal of large obstructing aspergillomas may sometimes be necessary.[15]

Coccidioidomycosis

Coccidioidomycosis is a fungal infection caused by the dimorphic fungus *Coccidioides immitis*, found principally in the soil of the southwestern United States. Endemic areas in the United States include southern California, Arizona, Texas, and New Mexico. Mexico and South and Central America are additional endemic regions. Human

infection is acquired by inhalation of airborne fungal spores. Most patients have a mild, self-limited illness characterized by upper respiratory tract symptoms; however, disseminated disease with more severe extrapulmonary symptoms is more common in immunocompromised patients (HIV, cancer, and transplant patients), infants, and non-Caucasian individuals.[17]

Disseminated coccidioidomycosis is typically characterized by infection of the skin, bones of the hand, feet, skull, and spine, as well as meningeal involvement. Genitourinary involvement is thought to occur through the hematogenous route. An autopsy series of 214 patients with disseminated disease described renal infection in 27%, prostatic infection in 2%, and epididymal involvement in 1%.[18] Immunosuppressive chemotherapy, lymphopenia, HIV, and organ transplantation have been described as some of the most important risk factors for disseminated disease. Maternal–fetal transmission, either transplacentally or perinatally, is rare, with only a handful of case reports in the literature.[19] Unfortunately, infants who acquire the disease in the postnatal period are reported to have a much higher mortality rate than older children and adults.

Genitourinary symptomatic presentation may occur simultaneously with pulmonary involvement, or may present more indolently, if at all. Often, diagnosis is delayed due to nonspecific or more latent presentations. Microscopic hematuria, pyuria, scrotal swelling, epididymal induration, and tenderness may be present in those with urinary and epididymal involvement. Coccidioidal infection of the kidney is typically confined to the cortex as small miliary granulomas or microabscesses. Large obstructive lesions within the renal pelvis do not occur as with other fungal infections.

The primary difficulty in the diagnosis of coccidioidomycosis infection is failure to consider the disease. Culture and serologic testing remain the gold standard for identification of infection. Tissue specimens may demonstrate coccidioidal spherules (Figure 8.5), which are pathognomonic for the disease, and the presence of surrounding granulomatous inflammation. Urine culture is very useful for establishing genital tract infection with *C. immitis*, as the fungus grows well on most culture medium.[20] Serologic testing with the mycelial phase antigen, coccidioidin, is a very reliable means of antibody testing. The radiographic findings of advanced renal coccidioidomycosis are generally similar to those of renal tuberculosis, characterized by infundibular stenosis, blunted or sloughed calyces, and calcified granulomas.

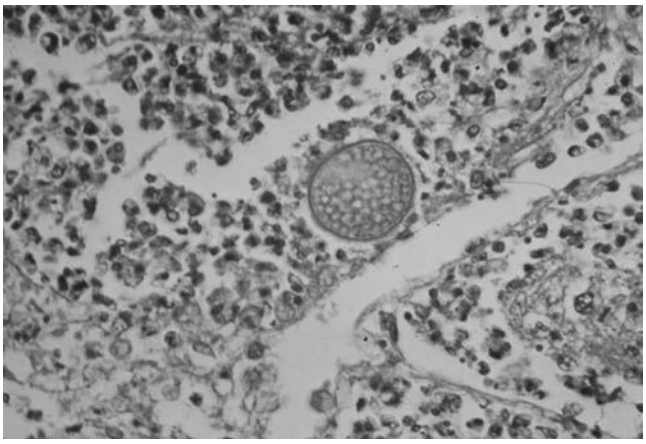

FIGURE 8.5 Mature spherule containing endospores of *C. immitis*. (Courtesy of http://phil.cdc.gov/phil_images/20030610/12/PHIL_480_lores.jpg.)

Treatment with prolonged antifungal chemotherapy is indicated for those at high risk for severe coccidioidomycosis and those with recognized disseminated infection. Amphotericin B is again the gold standard agent in pediatric patients with rapidly progressive disease. Oral azoles, such as fluconazole and ketoconazole, are alternative options. The management of isolated genital tract involvement has not been well defined in the literature. The overall treatment duration depends on the resolution of symptoms and signs, as well as the serologic response, with most practitioners administering antifungal therapy for a total of 2–3 months.

PARASITIC INFECTIONS OF THE URINARY TRACT

Schistosomiasis

Schistosomiasis is a tropical parasitic disease that infects nearly 200–300 million individuals globally, with the highest prevalence and intensity of infection primarily in children and adolescents. The two most common species are *Schistosoma haematobium* and *Schistosoma mansoni*. Urinary schistosomiasis, or bilharziasis, is a vascular parasitic infection caused by the blood fluke *S. haematobium*. The disease is endemic in Egypt and has spread to areas of Africa, Asia, South America, and the Caribbean. Prevalence is increasing in many areas, as population density increases and new irrigation projects provide broader habitats for vector snails. Imported cases into Europe have risen with the expansion of international travel. Rare cases are seen in the United States and almost always originate from an endemic area.

Humans are infected through contact with water contaminated with cercariae, the free-living infective stage of the parasite. These organisms emerge from infected snails and penetrate the intact human skin. The cercariae develop into schistosomula in the subcutaneous tissues and then migrate to the portal circulation, where they reach sexual maturity. The adult worms then migrate to the perivesical and periureteral venous plexus. Upon fertilization, female worms deposit eggs in the small venules, which eventually reach the lumen of the urinary tract. Eggs are passed into freshwater, where they hatch, infect freshwater snails, and begin the cycle anew (Figure 8.6). The entire life cycle ranges from 6 to 10 weeks in duration.

Humans become infected with *Schistosoma* after coming in contact with contaminated water. Children are most at risk due to activities such as swimming, bathing, and drinking contaminated water sources. Acute schistosomiasis occurs between 3 and 9 weeks after infection and coincides with deposition of eggs in the bladder wall.

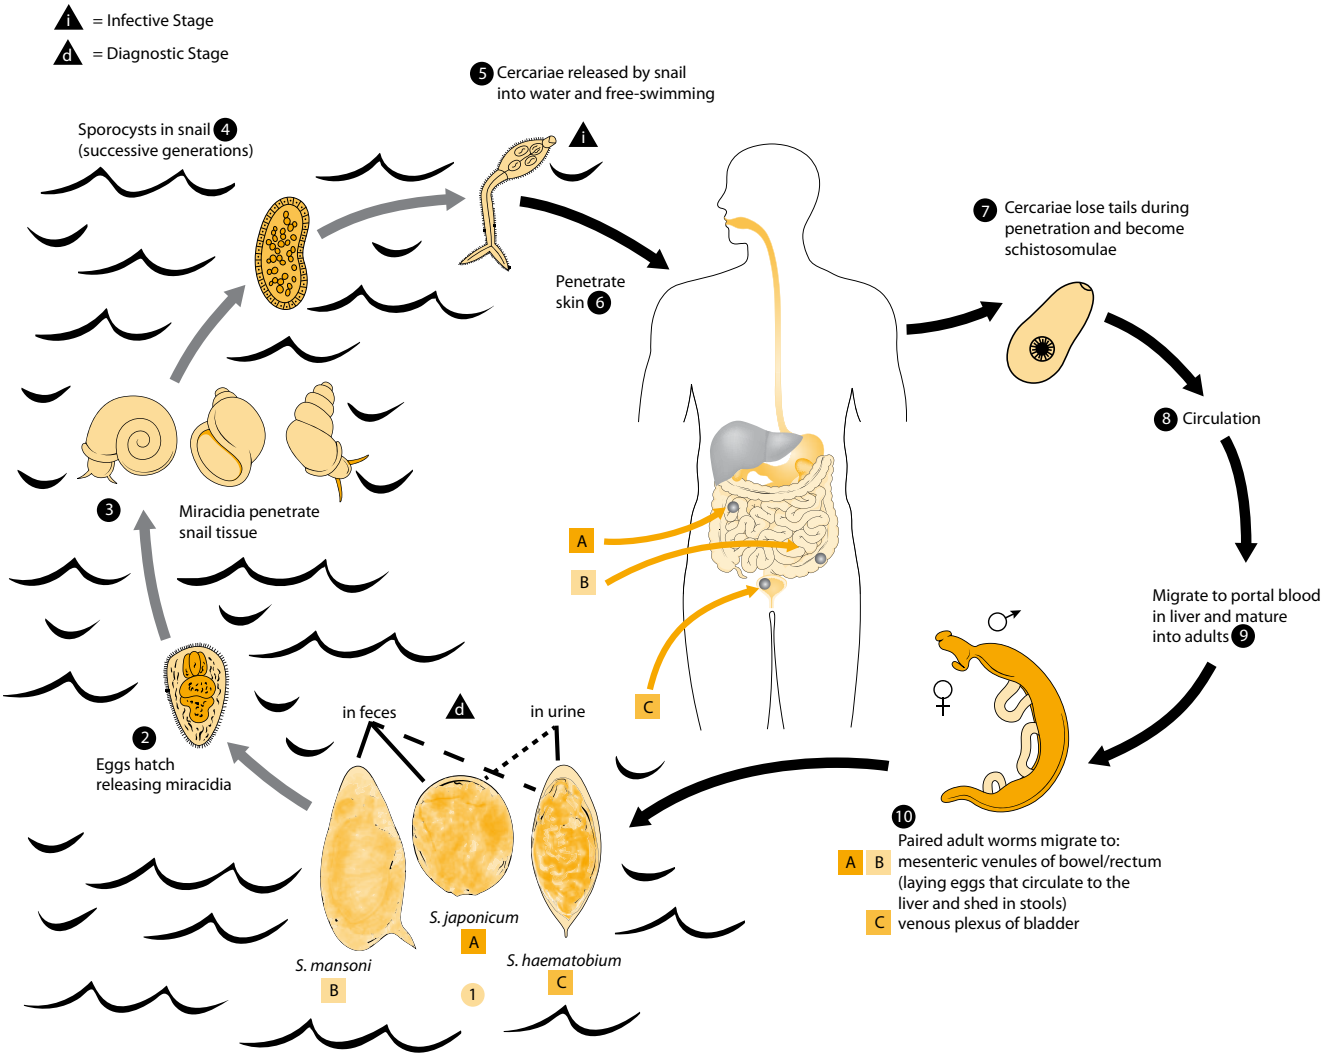

FIGURE 8.6 Life cycle of schistosomiasis parasite. (From the Centers for Disease Control and Prevention, U.S. federal government public domain archive image.)

The pathogenesis of schistosomiasis is due to the reactions to toxic, antigenic, and excretory products of the various developmental stages of the parasite.[21] The classic symptoms and signs are terminal hematuria, dysuria, leukocyturia, and nocturia. Hematuria can be so severe as to result in anemia. Severely infected patients may go on to develop obstructive uropathy with resultant renal failure. Chronic infection may lead to the most serious pathological consequences, namely, fibrosis, bladder contracture, and ureteral strictures. The disease process is insidious, and gross hydroureteronephrosis with renal insufficiency may occur before clinical symptoms appear. Persistent gross hematuria has been reportedly the most consistent clinical finding in endemic regions.

Vester et al. documented the prevalence of schistosomiasis infection in an endemic region of Mali by screening 824 villagers.[22] Infection ranged from 77% in adolescents to 51% in adults older than 40 years of age. Intensity of infection was generally low, with 91% excreting less than 100 ova per 10 mL of urine. Bladder wall thickening and irregularities, bladder masses, and dilation of the upper tracts were found ultrasonographically in approximately one-third of individuals. Bladder lesions were more frequent in children than adults and correlated well with the intensity of the infection in younger age groups.

Schistosoma eggs produce a marked eosinophilic infiltrate within the bladder wall. As the disease progresses, collagen infiltration and progressive bladder fibrosis occur. There is deposition of calcareous material and ultimately sclerosis of the bladder due to gradual calcification. Mucosal hyperplasia, squamous metaplasia, and epithelial dysplasia of the urothelium may occur at any stage of the disease process. Involvement of the trigone and bladder neck is most pronounced. Eventual bladder neck fibrosis may lead to outlet obstruction. Resultant urinary stasis and urinary infections can lead to the formation of bladder calculi, whereas chronic bladder irritation predisposes these patients to squamous cell carcinoma. Vesicoureteral reflux is commonly reported in up to 50% of these patients as a result of fibrosis and lateral displacement of the intramural ureter.

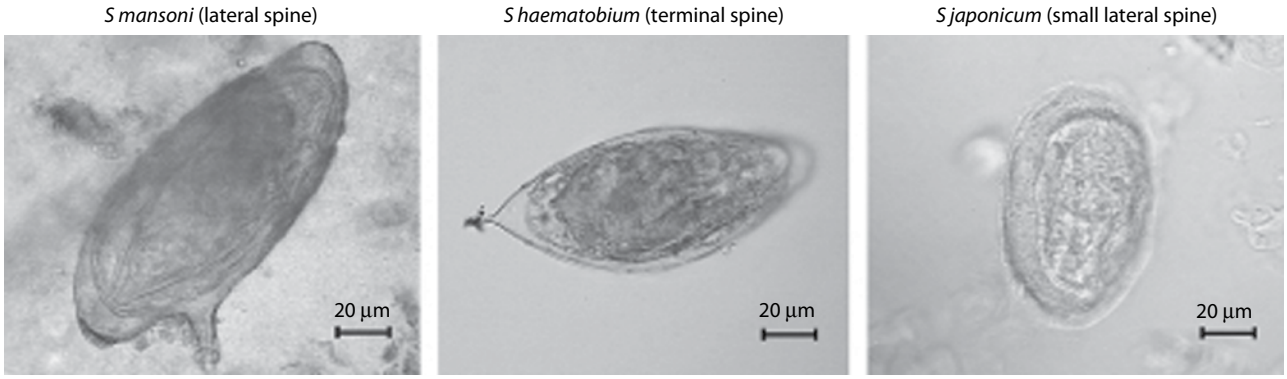

FIGURE 8.7 Microscopy of the various eggs of the *Schistosoma* species. (Courtesy of Gryseels B. *Lancet* 2006;368:1106–18.)

The gold standard for the diagnosis of schistosomiasis is established by the presence of terminal-spined eggs seen on microscopic examination of urine (Figure 8.7).[23] A 24-hour urine collection with microscopic examination of the urine concentrated by sedimentation, centrifugation, or filtration is typically recommended. The intensity of infection is expressed in terms of number of eggs per 10 mL of urine. Peripheral blood examination will usually show eosinophilia. Anemia may be present with chronic infection due to destruction of erythrocytes by the blood fluke.[24] Antibody-based assays by enzyme-linked immunosorbent assay (ELISA), indirect hemagglutination, or immunofluorescence are very sensitive; however, they cannot distinguish between a history of *Schistosoma* exposure and acute infection.[23] Cystoscopy and bladder biopsy may be performed in cases of negative urinalysis, as well as to further characterize bladder involvement.

Abdominal plain film, as well as ultrasonography, allows visualization of bladder, ureteral, and renal involvement. Calcification of the bladder wall, described as an "eggshell appearance" on plain film, is classic for chronic urinary schistosomiasis (Figures 8.8 and 8.9).[25] Hydronephrosis secondary to ureteral stricture may be found on imaging studies of the urinary tract. On cystoscopic evaluation of the bladder, bilharzial tubercles predominate over the trigone and posterior bladder wall. In patients with chronic disease, fibrosis and calcification of these parasitic nodules in the submucosa form dull, granular "sandy patches" that resemble grains of sand under water. Chronic schistosomiasis has been implicated in the later development of squamous cell carcinoma of the bladder (Figure 8.10).

Management of children with schistosomiasis should be based on an appreciation of the intensity of the infection and the extent of the disease. There are several drugs available for the treatment of urinary schistosomiasis. Most carry with them significant side effects. Praziquantel is currently the drug of choice. It is effective against all species of *Schistosoma*. The recommended regimen is to administer the drug orally as a single or divided dose of 40–60 mg/kg body weight.[26] The side effects of the drug are often quite mild, notably nausea, emesis, malaise, and abdominal pain. After a single dose, 70%–100% cease to excrete the parasitic ova. At times, a single repeat dose 6–12 weeks later is recommended to treat prepatent infections.

Surgical intervention in schistosomiasis should be reserved until the effects of medical management are

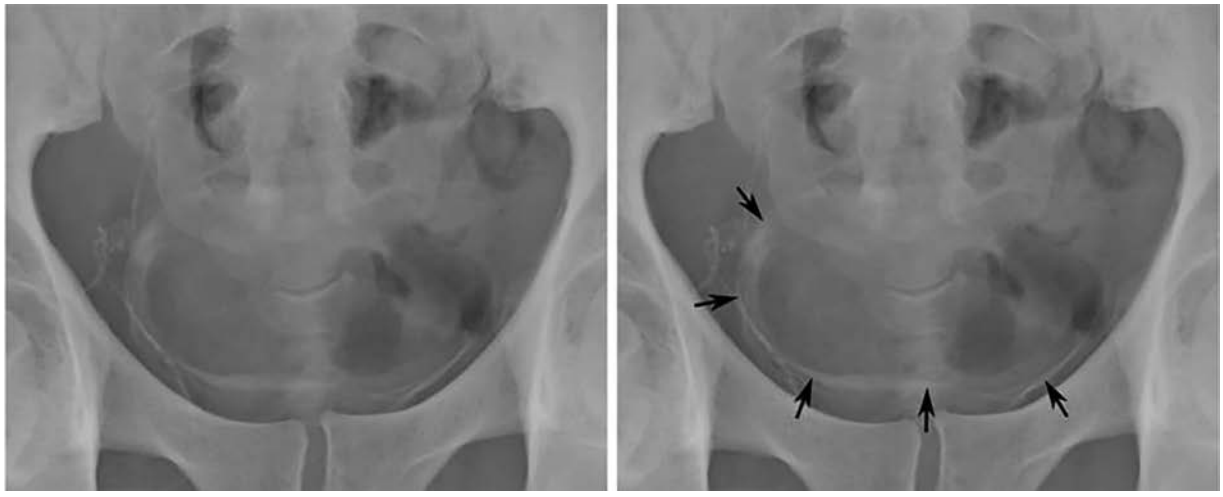

FIGURE 8.8 Plain abdominal film of urinary schistosomiasis. Note the classic eggshell calcification of the bladder wall. (From WikiMedia Commons, online repository of freely licensed media.)

assessed. Fibrosis and contracture of the bladder may require autoaugmentation, intestinal augmentation, or bladder replacement. Bilharzial strictures of the lower ureter can produce obstructive uropathy. Unfortunately, the extensive fibrosis of the ureteral wall and the bladder mucosa usually precludes traditional ureteroneocystostomy by submucosal tunneling. Bazeed et al. suggest a method of partial flap ureteroneocystostomy to alleviate the obstruction.[27] They report it to be effective in improving or stabilizing the upper tracts in 83% of individuals. Vesicoureteral reflux may develop in as many as 30% of these individuals after surgery.

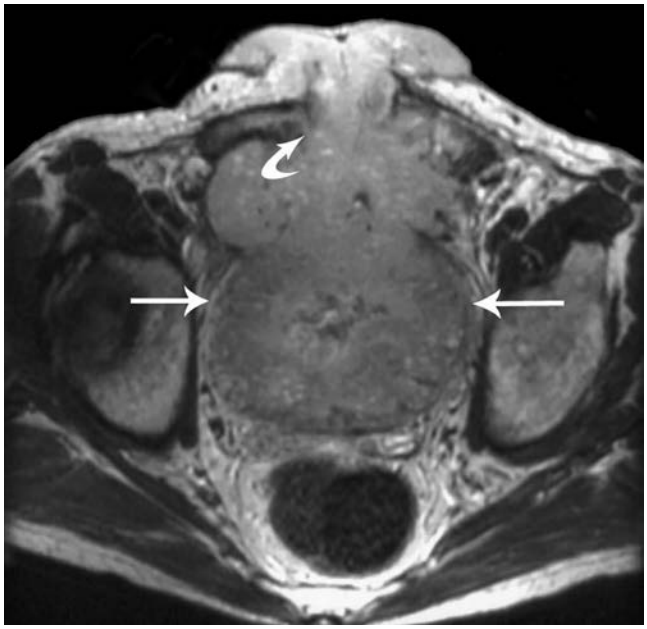

FIGURE 8.10 Invasive squamous cell carcinoma. Axial T2-weighted magnetic resonance image shows a soft tissue mass (straight arrows) filling the pelvis and obliterating the normal bladder lumen. The mass is locally aggressive and has eroded through the abdominal wall (curved arrow). (Courtesy of Wong-You-Cheong JJ et al. *Radiographics* 2006;26:553–80.)

Echinococcosis

Echinococcosis, or hydatid cyst disease, is the most prevalent human cestode infection in the world. There is virtually no part of the human anatomy that is immune from hydatid cyst disease. It is caused by the dog tapeworm *Echinococcus granulosus*. Although uncommon in the United States, it is endemic in the sheep-raising areas of the world, such as Argentina, Australia, Spain, and Greece.

Humans are an intermediate host for the larval eggs of the adult tapeworm. The adult tapeworm lives in the intestinal tracts of dogs and sheds larval eggs, which are excreted in the dog feces. Humans, as well as sheep, cattle, and pigs, may accidentally ingest these larval eggs through orofecal contamination. Dogs initially acquire the disease by swallowing the parasitic scolices in their food, which have become contaminated with the encysted parasite in the liver and lungs of sheep. This completes the life cycle of the parasite.

In humans, the larval eggs pass through the intestinal wall and are widely disseminated throughout the body. Dissemination may occur by direct, vascular, or lymphatic invasion.[28] The primary organ affected in humans is the liver. Genitourinary involvement has been documented in the kidney, ureter, bladder, prostate, and epididymis.[29] The most common location for genitourinary hydatid cyst disease in humans is the kidney. It is estimated that approximately 3% of all echinococcal infections involve the kidney.[30]

The largest series of pediatric echinococcosis was reported by Auldist and Myers, who documented 114 cases of hydatid cyst disease.[31] Children of all ages were infected; however, manifestations of the disease were infrequently evident in children under 5 years of age. This is probably a result of the slow growth pattern of the hydatid cyst. The growth rate of hydatid cysts is estimated at 1 cm/year.[32] The cyst is typically very large at the time of initial presentation. The most common site of genitourinary infestation in the pediatric population is also the kidney. Hydatid cysts of the kidney usually present as a painful flank mass. Microscopic hematuria is present in the majority of the cases. Acute flank pain may be caused by rupture of the hydatid cyst into the collecting system. The passage of scolices (daughter cysts) may be associated with gross hematuria and urinary obstruction.[33]

Ultrasonography has proved to be the most valuable tool in the diagnosis of hydatid disease. Hydatid cysts are easily demonstrated on ultrasonographic evaluation of the abdomen in children. The coexistence of hydatid disease in other organs often assists in the diagnosis. Plain films or CT of the abdomen and pelvis may also reveal calcification within the walls of these cysts (Figure 8.11a–f).[34]

As humans are infected with only an intermediate stage of *Echinococcus*, the actual parasite cannot be

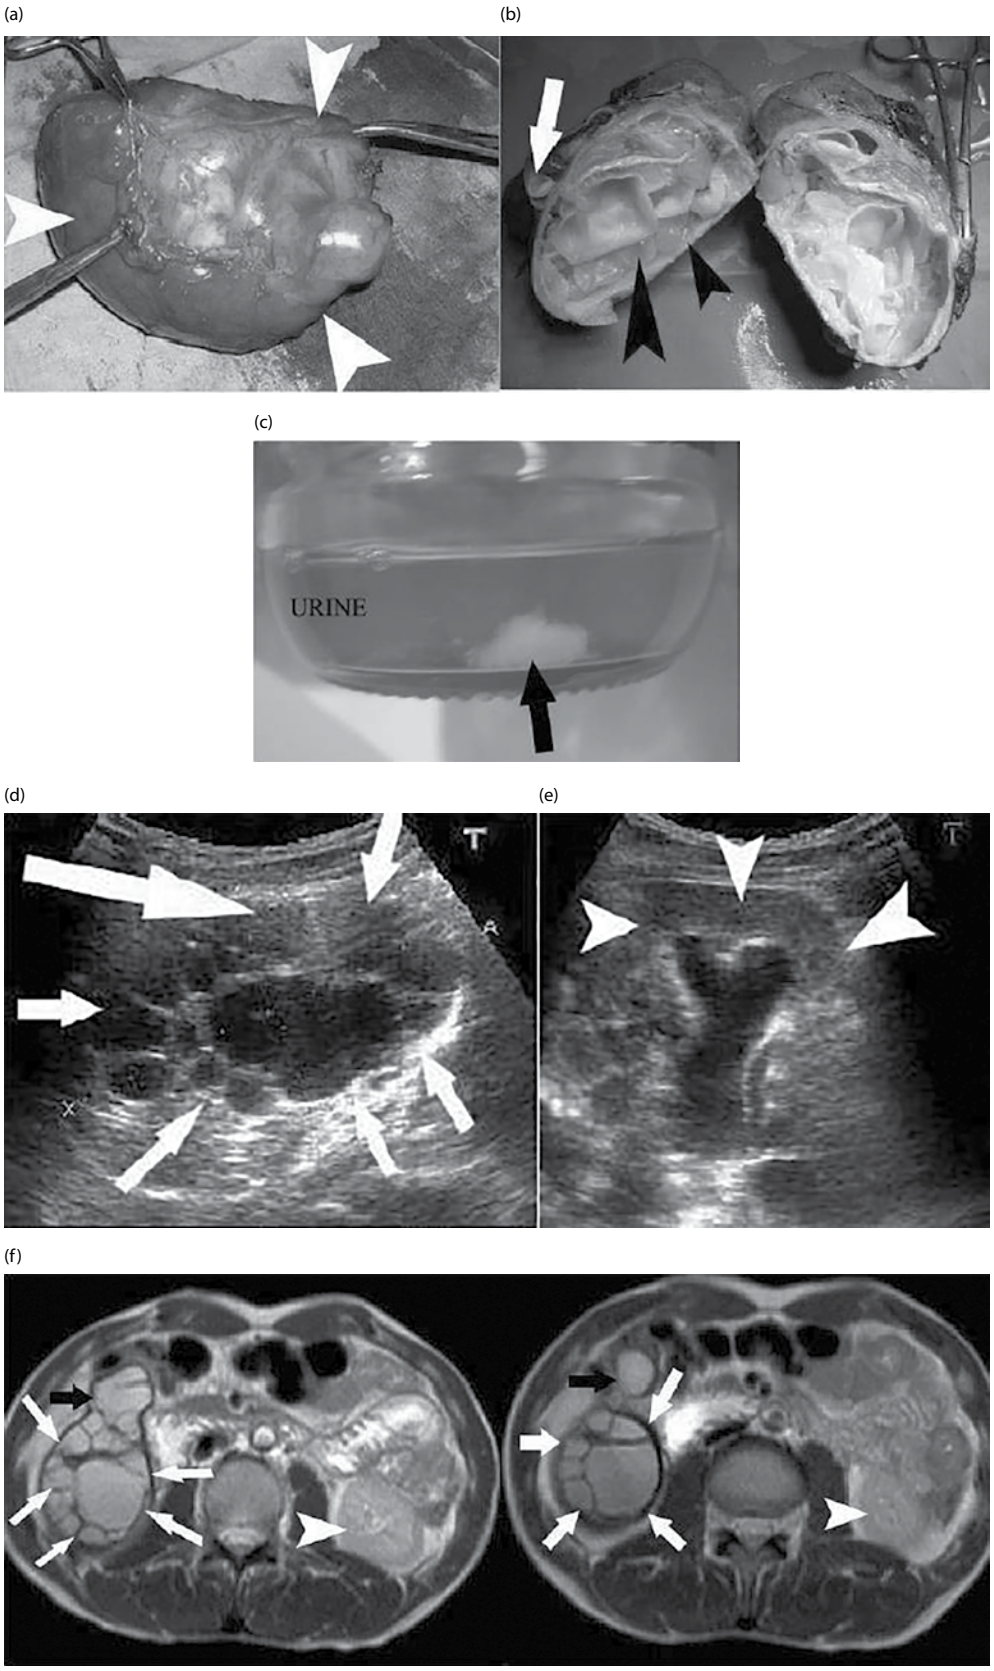

FIGURE 8.11 Renal echinococcus. (a) Postoperative nephrectomy gross specimen. (b) Cut section of kidney with hydatid cysts. (c) Urine specimen revealing hydatiduria. (d) Kidney replaced by multiseptated hydatid cysts, as seen on renal ultrasound. (e) Upper-pole hydronephrosis, as seen on renal ultrasound. routinely recovered from any easily accessible body fluid. If the hydatid cyst has ruptured into the collecting system, the recovery of scolices from the urine is pathognomonic for genitourinary echinococcosis. Serologic studies can also be useful in confirming the diagnosis of echinococcosis. Eosinophilia is reportedly present in approximate one-third of the children affected with echinococcosis. Indirect hemagglutination and ELISA testing are the most sensitive immunologic methods to diagnose human hydatidosis; however, false-positive reactions with other parasitic infections are possible.[28] Immunoelectrophoresis to detect specific antibodies against antigens isolated from hydatid cyst fluid is currently the most specific method of diagnosis of echinococcosis.[35]

Albendazole is the preferred drug for medical management of cystic hydatidosis. This drug therapy (15 mg/kg/day divided in three doses for 28 days) may be repeated for as many as four courses with 15-day drug-free intervals. A positive response may be seen in 40%–60% of pediatric patients treated.[32] Ultrasonographic indications of successful therapy include flattening of the cyst, increase in echogenicity, and detachment of membranes from the cyst capsule. The factors predictive of success with chemotherapy are age of the cyst (>2 years old), low internal complexity of the cyst, and small size.[36]

Although previously thought to be contraindicated because of the risk of anaphylaxis, percutaneous drainage of cysts under ultrasound guidance during albendazole therapy has become increasingly more successful for complete resolution of cystic disease. Spillage of cyst fluid is uncommon during aspiration. Nevertheless, systemic anaphylactic reactions are always possible with spillage of cyst fluid.

Surgical therapy is also an option for solitary lesions or failed medical management. Considerable care must be taken at the time of surgical resection to ensure that there is no rupture of the cyst or spillage of cyst fluid during removal, as viable protoscolices may contaminate the surgical field, each capable of forming a secondary cyst wherever it lodges. There is also a risk of developing anaphylaxis as a result of spillage of cyst fluid at the time of surgical resection.

Enterobiasis

Pinworm infestation (enterobiasis) is the most common helminth infection in the United States, as well as Western Europe. It is caused by the nematode *Enterobius vermicularis*. Humans are the only host, and are infected by direct anus-to-mouth transfer of eggs, which are usually carried on fingernails, clothing, or bedding. The larvae hatch in the duodenum, and the adult worm ultimately attaches to the mucosa of the large intestine, namely, the cecum, appendix, and nearby bowel (Figure 8.12). The gravid adult female worm ultimately migrates at night to the rectum and deposits her eggs in the perianal and perineal skin. Perianal irritation during egg deposition by female worms induces scratching. Eggs carried underneath the fingernails promote reinfection and autodissemination, and transfer of the disease to others. Often, the eggs are deposited in adjacent orifices as well, most commonly in the female genitourinary tract, causing recurrent UTIs and vulvovaginitis. Pinworm infection is very common among school-aged children. The peak age of infection is between 5 and 14 years of age. The estimated U.S. prevalence has been reported to be as high as 42 million cases.[37]

Enterobiasis has been implicated as a factor in acute and chronic UTIs. In a study of female children, Kropp et al. demonstrated that 22% of girls with documented UTIs had pinworm infestations compared with only 5% of an age-matched control population.[38] In a study by Ok et al., they estimated the prevalence of *Enterobius* in school-aged children with concurrent UTIs to be approximately 36%, compared with 16% in their control group.[39] They also report that the recovery of pinworms from the perianal region is higher in girls with enteric organisms present on a swab of their introitus.

The most common presentation of enterobiasis is perineal or perianal pruritis, often worse at night. Other associated symptoms commonly found are abdominal pain, anorexia, insomnia, dysuria, enuresis, vaginal discharge, and vulvovaginitis. Rarely, ectopic infections may result in endometritis, salpingitis, urethritis, epididymitis, pyelitis, pelvic inflammatory disease, or enterocutaneous fistulas. However, approximately one-third of infested children are entirely asymptomatic.

The diagnosis is typically made based on clinical history. However, definitive diagnosis is established by either finding the parasitic eggs or recovering the worms. The eggs can be easily detected by pressing adhesive tape against the perianal region early in the morning prior to bathing or defecation. The tape is then applied to a glass slide and it is examined under low-power magnification (Figure 8.13). Often, repeated examinations, usually totaling three, are necessary to make a negative diagnosis. On occasion, the threadlike yellow-white adult worms may be spotted in the stool or on toilet paper. Laboratory evaluation is typically normal, with a rare eosinophilia detected in cases of invasive disease.

Drug therapy should be given to all infected individuals. Mebendazole (100 mg single oral dose), with a repeat dose at 2 weeks, is the drug of choice. However, while its efficacy for gastrointestinal infection is cited to be around 96%, its poor absorption renders it less effective for genitourinary infections.[40] Alternative agents include ivermectin, piperazine citrate, pyrvinium pamoate, and albendazole. Kropp et al. report a greater than 50% success rate in eradicating multiple recurrent UTIs in girls with concomitant pinworm infestation when the infestation is definitively treated.[38] Unfortunately, reinfection is quite common, and adequate management typically requires the entire household to be treated simultaneously.

OTHER INFLAMMATORY DISEASES OF THE URINARY TRACT

Chlamydial Infections

Chlamydial infections in children include a spectrum of disease: perinatally transmitted infections comprising neonatal conjunctivitis, infantile pneumonia, respiratory or genital tract infections in older children, and sexually transmitted diseases in adolescents.[41] *Chlamydia*

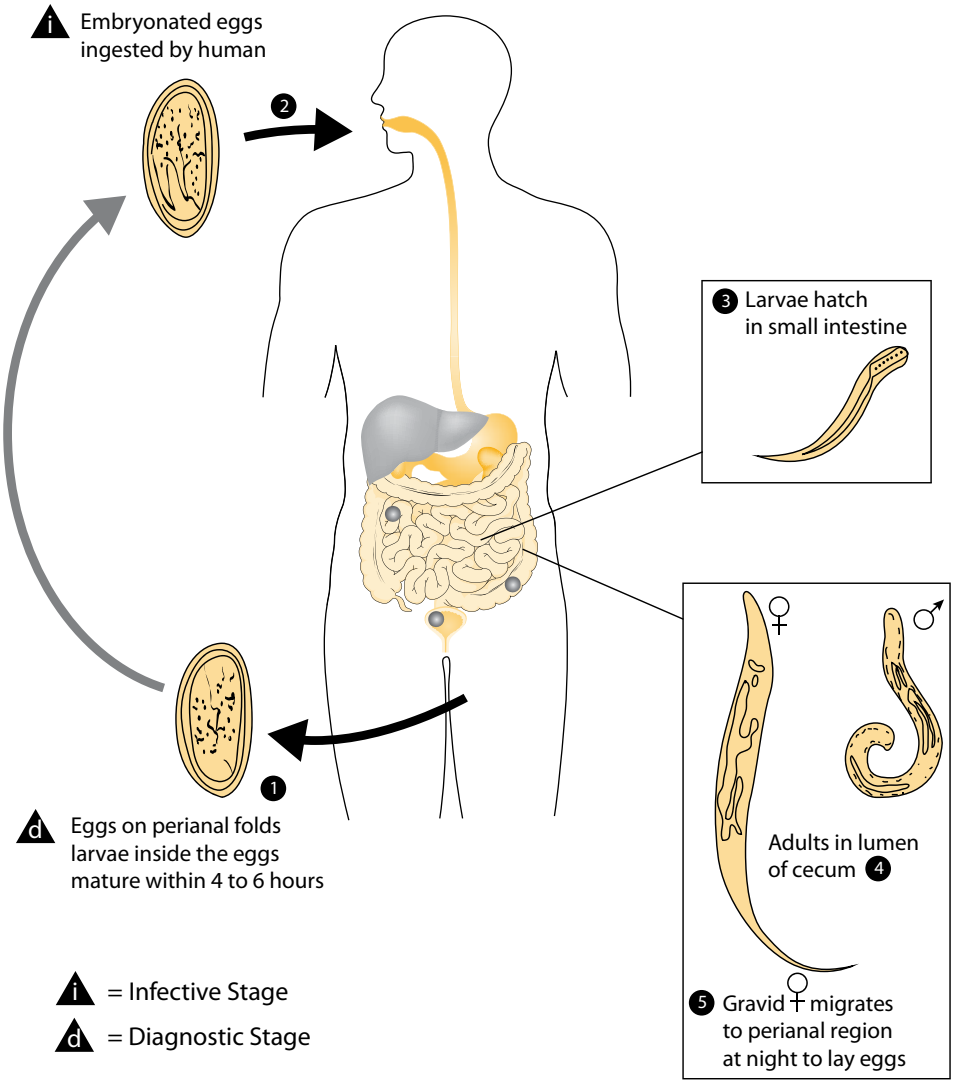

FIGURE 8.12 Life cycle of *E. vermicularis*. (Courtesy of the Centers for Disease Control and Prevention, http://www.dpd.cdc.gov/dpdx/images/ParasiteImages/A-F/Enterobiasis/Enterobius_LifeCycle.gif.)

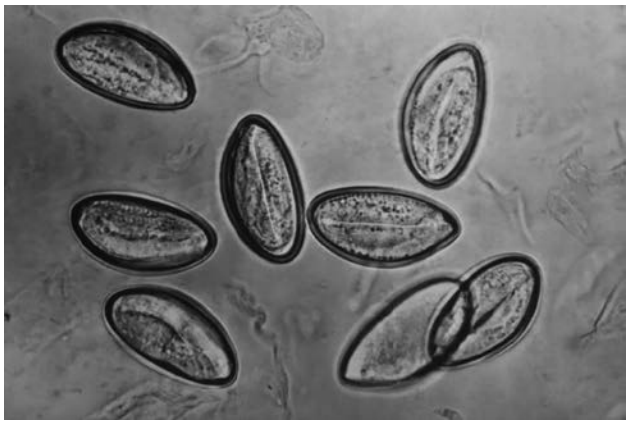

FIGURE 8.13 Enterobiasis. Demonstration of the round worm captured on cellulose tape and viewed under microscopy. (Courtesy of the Centers for Disease Control and Prevention, http://www.cdc.gov/parasites/pinworm/).

trachomatis is the only one of the four chlamydial species that commonly infects the human genitourinary tract and causes human oculogenital diseases. *C. trachomatis* is thought to be responsible for the majority of nongonococcal urethritis and pelvic inflammatory diseases in adolescents.

Chlamydia are obligate intracellular bacteria that are distinguished by a unique developmental cycle. Although they possess their own DNA and RNA, contain ribosomes, and have a cell wall, they lack the ability to generate adenosine triphosphate (ATP) and are therefore considered an energy parasite. *Chlamydia* alternate between an infectious, metabolically inactive extracellular form, the elementary body (EB), and a noninfectious, metabolically active form, the reticulate body (RB). It is the EB that binds to specific receptor proteins on the cell membrane and enters the cell by endocytosis. Within 12 hours of ingestion, the EB then differentiates into the RB form and undergoes binary fission. This results in the

typical intracytoplasmic inclusion bodies pathognomonic of a chlamydial infection. After approximately 36 hours, the RB differentiates back into an EB and is then released from the cell by a process of exocytosis.

Cervical chlamydial infections are reported in approximately 5%–30% of pregnant women. Active chlamydial infections at the time of pregnancy may be transmitted to the infant at the time of vaginal delivery. Genitourinary sites of perinatal transmission include the vagina and urethra. The risk of vertical transmission from mother to child is about 50%.[42] Neonatal conjunctivitis develops in 20%–50% of infected deliveries, while infantile pneumonia occurs in 5%–20%. Perinatally transmitted infections of the vagina, urethra, or rectum may become sites of colonization that persist for several years with minimal or no symptoms at all; therefore, the presence of *Chlamydia* is not necessarily an indication of child abuse. Currently, prenatal screening and treatment of pregnant women is the most effective strategy for preventing neonatal chlamydial infection.

The most common chlamydial infections in older infants and children include urethritis, vaginitis, and cervicitis in girls and nongonococcal urethritis and epididymitis in boys. In boys, the most common symptom of chlamydial urethritis is a clear mucoid urethral discharge. It may be associated with urinary urgency, frequency, dysuria, and scrotal pain and tenderness. In girls, acute inflammatory changes in the vagina or cervix may lead to mucopurulent discharge. Unfortunately, chlamydia is often a silent disease, only to later manifest with the long-term consequences of pelvic inflammatory disease, such as chronic pelvic pain, ectopic pregnancy, or infertility.

The definitive diagnosis of chlamydial infection includes isolation by culture of the organism from the urethra in boys and endocervical region in girls. Several nonculture methods have also been approved by the U.S. Food and Drug Administration (FDA) and include a direct fluorescent antibody test or an enzyme immunoassay. A midstream or first void urine sample is effective at capturing the chlamydial organism for the nucleic acid amplification test (NAAT). In fact, NAATs for the detection of *C. trachomatis* and *Neisseria gonorrhoeae* have largely replaced culture in many laboratories. However, none of the currently available NAATs have FDA approval for use in conjunctival or nasopharyngeal specimens from infants. Because of its high specificity and sensitivity, direct cell culture is the only test that should be used to establish the presence or absence of infections in cases with legal implications, such as pediatric sexual abuse.

Antibiotics are the mainstay of therapy for chlamydial infections in children. These antimicrobials, usually sulfonamides, macrolides, and tetracyclines, are the most common agents; tetracyclines should not be administered to children under the age of 8 years because of the resulting dental discoloration that may occur. Oral erythromycin therapy (50 mg/kg/day in four divided doses administered for 14 days) has been recommended for both neonatal inclusion conjunctivitis and chlamydial pneumonia. Sulfonamide antimicrobials are an acceptable alternative in infants at least 3–4 weeks old. Azithromycin is considered by many to be the treatment of choice of *C. trachomatis* genitourinary infection because it may be administered as a single-dose treatment. Doxcycline, a tetracycline antimicrobial, is typically given for a 1-week course. Erythromycin and ampicillin are alternative options for pregnant women with active chlamydial infections.

Inflammatory Hemorrhagic Cystitis (Viral Cystitis)

Viral cystitis causes irritative voiding symptoms and hematuria in infants and children. In the toilet-trained older child, it is characterized by symptoms of urinary frequency, urgency, dysuria, incontinence, and gross hematuria with a negative urine culture for bacterial organisms. Severe hemorrhagic viral cystitis is seen more frequently in immunosuppressed pediatric patients, most commonly those who have undergone HSCT or children infected with HIV. Viral infections can often be life threatening in these immunocompromised patients. The incidence rate of hemorrhagic cystitis in the HSCT pediatric population has been cited to range from 10% to 70%.[43]

The usual causative viruses are adenovirus types 11 and 21, influenza A, polyoma BK virus, and cytomegalovirus. Adenoviruses are a family of double-stranded, nonenveloped DNA viruses transmitted through droplet and fecal–oral spread. Adenovirus infections, in the form of asymptomatic or mild self-limited respiratory infection, are exceedingly common in the general pediatric population. In the immunocompromised host, however, adenovirus can cause severe localized disease manifestation, including pneumonitis, hepatitis, colitis, and severe hemorrhagic cystitis.[44] At present, adenovirus is the most common cause of viral hemorrhagic cystitis in immunocompromised children. In study populations, male patients outnumber female patients by a ratio of 2–3:1. It may occur as a result of a new exposure causing a primary infection or reactivation of latent disease. Viral shedding may continue throughout the duration of the illness, lasting a median duration of 2 weeks (range 1–111 days).[45]

There are a number of clinical tests available for the specific diagnosis of adenovirus infection. Nearly all adenovirus serotypes cause a distinct cytopathic effect (CPE) in human epithelial cell lines, and thus can be detected by routine viral culture from collected urine specimen. Direct detection of adenovirus antigens in clinical samples may be performed by an adenovirus-specific ELISA or immunofluorescence assay. These assays are more rapid but less sensitive than viral culture for the detection of most serotypes and have been shown to be less sensitive in the immunocompromised population. Quantitative PCR in blood and urine has been increasingly utilized in pediatric HSCT patients, both for diagnosis and to assess response to treatment. Radiographic changes within the bladder are remarkable and often resemble that of a bladder sarcoma, and ultrasonography may show a diffusely thickened bladder wall (Figure 8.14).

Human polyoma BK virus belongs to the genus *Polyomaviridae*, which consists of nonenveloped DNA

FIGURE 8.14 Inflammatory hemorrhagic cystitis—diffusely thickened bladder wall. (Courtesy of Wong-You-Cheong JJ et al. *Radiographics* 2006;26:1847–68.)

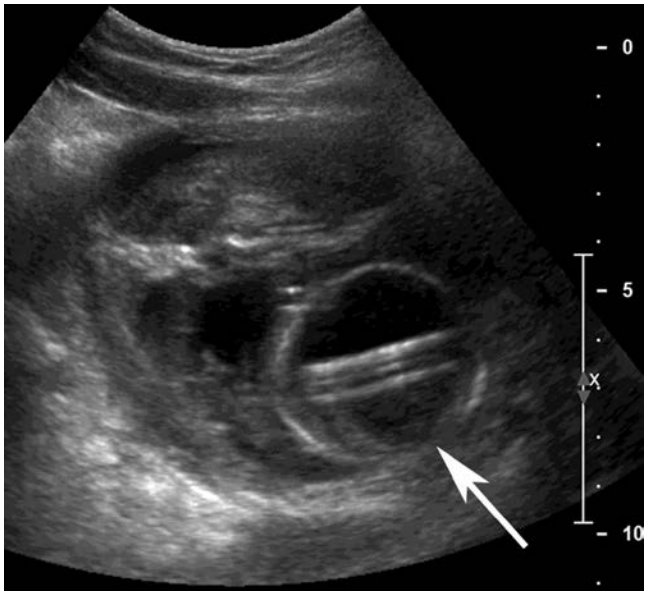

FIGURE 8.15 Bone marrow transplantation patient with diffuse bladder thickening and extensive intraluminal clot. (Courtesy of Hollingsworth CL et al. *Radiology* 2008;248:348–65.)

viruses. It is a ubiquitous virus, present in nearly 80% of the population. Primary infection is usually asymptomatic. BK virus is frequently identified in the urine of HSCT patients with hemorrhagic cystitis.[46] The diagnosis of BK viruria is made by identification of epithelial cells within the urine containing intranuclear inclusion bodies suggestive of BK virus and a positive PCR test for BK virus in the urine. Arthur et al.[47] report that the viruria occurred exclusively in patients who were seropositive at transplantation, indicating a reactivation of the latent virus from dormant sites. BK viremia has also been correlated quantitatively with posttransplant hemorrhagic cystitis. Patients with plasma BK virus greater than 104 copies/mL appeared to be at higher risk of viral hemorrhagic cystitis. Many immunocompromised patients do not respond to traditional therapies for hemorrhagic cystitis and may develop extensive and recalcitrant clot retention (Figure 8.15) and ultimately progress to acute renal failure.

Different strategies have been advocated for the management of severe intractable viral hemorrhagic cystitis. Treatment recommendations are often based on experience from case reports or small series studies. In mild cases, treatment may begin with aggressive fluid hydration, pyridium for analgesia, and forced diuresis with furosemide. In all patients with severe hemorrhagic cystitis, correction of thrombocytopenia and coagulopathy is imperative, and may decrease the severity of the hematuria. The use of several antiviral agents, such as ribavirin, ganciclovir, and cidofevir, as well as human leukocyte transfusions, has all been reported in the literature.[45] Ribavirin, an intravenous antiviral agent, has had the greatest reported success in children with acute adenovirus hemorrhagic cystitis. Renal excretion, accounting for nearly one-third of the drug's elimination, ensures high levels of ribavirin in renal and bladder tissues.[44] Its most common side effect is a mild reversible anemia. Cidofevir has been used in both intravenous and intravesical administrations. The most common side effect, nephrotoxicity and resultant renal failure, has hampered its systemic use in the bone marrow transplantation population. Case reports of intravesical instillation of cidofevir (5 mg/kg diluted in 100 mL of saline, slowly instilled via a Foley catheter, which is clamped for 1 hour, BID) have demonstrated marked reduction in hematuria and clearance of the virus on subsequent urinary PCR testing.[48]

Continuous bladder irrigation with saline has also been used in cases of hematuria with clot retention. Several compounds, alum, phenol, silver nitrate, formalin, and prostaglandins, have been tried in intravesical instillation regimens. Aluminum toxicity and long-term complications of formalin instillation, which include bladder fibrosis, urinary frequency and/or incontinence, vesicoureteric reflux, and obstruction, make these instillations less desirable options. Prostaglandins have been advocated due to their role in vasoconstriction and platelet aggregation of the vascular epithelium, their cytoprotective effect on bladder mucosa, and their low toxicity and good tolerability profile. Cesaro et al., in a large multicenter pediatric retrospective study, showed the beneficial effects of hyperbaric oxygen therapy (HOT) in severe, refractory cases of viral hemorrhagic cystitis.[49] Cystotomy, cystoscopy with clot evacuation, vesicostomy, and even cystectomy with urinary diversion or vesical artery embolization are treatments reserved for refractory life-threatening cases only.

Eosinophilic Cystitis

EC is a rare inflammatory disorder of the urinary bladder, characterized by irritative voiding symptoms. There are less than 30 pediatric case reports in the reported literature. The disease is characterized by a transmural

inflammation of the bladder wall predominated by eosinophils, and fibrotic changes with or without muscle necrosis. Symptoms are nonspecific, with the most common being dysuria, frequency, hematuria, and suprapubic discomfort.[50] Children may present with a palpable suprapubic mass on physical examination. Occasionally, this may be mistaken for an invasive bladder tumor or pelvic sarcoma.[51] EC has been reported to occur in all age groups, with a slight male preponderance in children. Associated conditions include history of allergy, asthma, atopy, history of bladder trauma, bladder surgery, parasitic infections, autoimmune disorders, and intravesical chemotherapy.

The true etiology of EC remains unknown. An immunoglobulin E (IgE)–mediated allergic cause has been suggested given the strong allergic histories of these patients. Food allergens, drugs, and other substances have been implicated.[52] It has been postulated that various inciting agents, such as bacteria and foreign protein, act as antigenic stimuli in the bladder to produce an eosinophilic infiltration. These antigens form immune complexes, resulting in the release of enzymes and cytokines that enhance the inflammatory cascade and its resultant bladder tissue damage.

Typical presentations are characterized by irritative voiding complaints, dysuria, frequency, hematuria, and suprapubic pain. Less common symptoms include nocturia and urinary retention.

Rare presentations include gastrointestinal symptomatology due to eosinophilic gastroenteritis.[53] Physical examination is usually unremarkable, with the exception of rare cases of children presenting with palpable lower abdominal masses. Urinalysis commonly shows proteinuria, pyuria, and microscopic hematuria. Eosinophils in the urine or peripheral blood eosinophilia, although diagnostically helpful, are infrequently found. Elevated serum levels of IgE have been reported in the literature.[54] Urine cultures are typically negative.

Imaging studies of the bladder usually begin with ultrasonography. Irregular focal or diffuse thickening of the bladder wall may be evident, as well as hydronephrosis, hydroureter, and infiltrative bladder masses. A cystic form of EC may be seen as well (Figure 8.16).[25] The definitive diagnosis is established by cystoscopy and bladder biopsy. Cystoscopic findings include erythematous, velvety, raised plaques. The mucosa is often edematous with areas of ulceration.[53] These findings are nonspecific and may be confused with other forms of cystitis and neoplastic conditions, such as interstitial cystitis, tubercular cystitis, carcinoma in situ, and bladder rhabdomyosarcoma. Tamai et al. reported the MRI findings of a young girl with EC, being characterized by near-circumferential thickening of the bladder wall with relative sparing of the dome, and distinctly low-signal intensity on T2-weighted series consistent with fibrosis and increased tissue cellularity.[55]

Bladder biopsy shows a classic eosinophilic infiltration predominantly in the lamina propria, as well as the deeper muscle layers of the bladder wall (Figure 8.17). There may be focal muscle necrosis or significant detrusor fibrosis, resulting in a contracted bladder. Giemsa stain for eosinophils and trichrome stain for muscle fibrosis are helpful in making the diagnosis.[56] Electron microscopy is also a useful diagnostic aid.

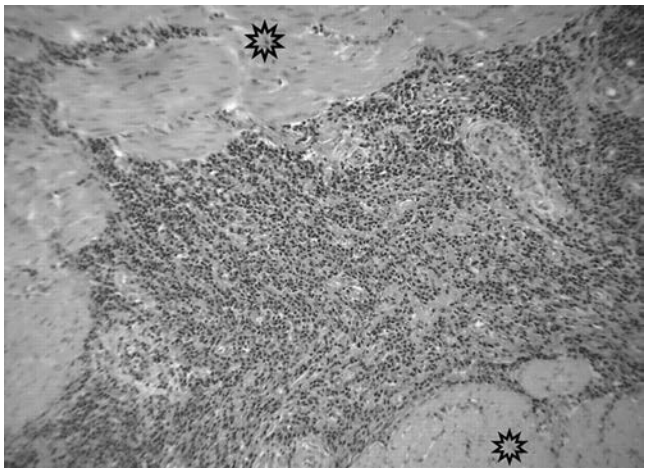

FIGURE 8.16 EC. Photomicrograph demonstrating an intense infiltration of eosinophils deep within the muscularis propria. (Courtesy of Wong-You-Cheong JJ et al. *Radiographics* 2006;26:1847–68.)

The treatment of EC involves removing the antigenic stimulus, if present and identifiable. A formal allergen skin test may aid in the identification of the antigenic stimulus

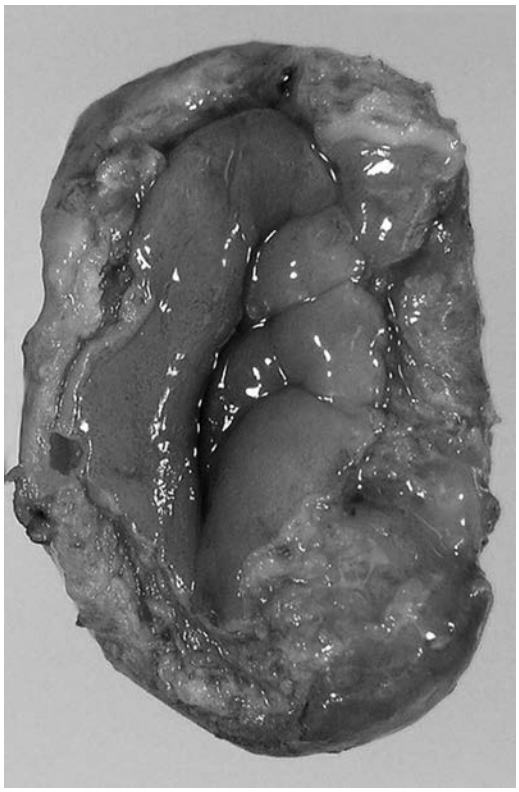

FIGURE 8.17 EC. Bladder gross specimen, cut section, demonstrating circumferentially thickened bladder wall. (Courtesy of Wong-You-Cheong JJ et al. *Radiographics* 2006;26:1847–68.)

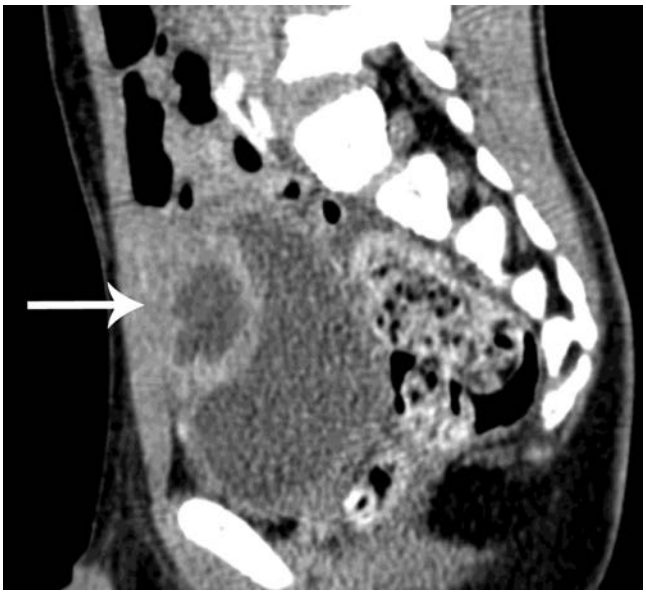

FIGURE 8.18 EC. Contrast-enhanced CT images show a thick-walled cystic mass (arrow) arising from the anterior dome of the bladder. (Courtesy of Wong-You-Cheong JJ et al. *Radiographics* 2006;26:1847–68.)

in the pediatric population. When no obvious cause is identified, initial management with nonsteroidal anti-inflammatory drugs, as well as antihistamines, has been used with good results. Patients who show no response to these agents have also been successfully treated with oral corticosteroids. Other case reports cite success with alternative agents, including silver nitrate and cyclosporin A.[53] Refractory cases with resultant bladder fibrosis and obstructive uropathy are quite rare, but have necessitated more radical therapy with partial cystectomy and bladder augmentation (Figure 8.18).[57]

The prognosis for children with EC is generally very good. Almost all reported cases in the literature resolved within 12 weeks. Despite the apparent self-limited course of EC, it should be kept in mind that recurrence and even unremitting progression of this disease are possible. Documented recurrences have been reported several years after the initial event. It has been hypothesized that local surgical trauma to the bladder may be the cause for recurrence. A recommendation for pretreatment with steroids and antihistamines prior to bladder surgery has been made for patients with a previous history of EC.[58]

Malacoplakia

Malacoplakia is a rare benign chronic inflammatory condition thought to be a consequence of a defective phagolysosomal system. It was first described by Michaelis and Gutmann in 1902. It clinically manifests as single or multiple plaque-like tumors that may appear in any organ system. The name *malacoplakia* is derived from the Greek words *malakos* and *plakos*, meaning soft and plaque. In the adult population, malacoplakia affects the bladder in about 40% of cases.[59] Conversely, in the pediatric population, a wide variety of organs, such as the

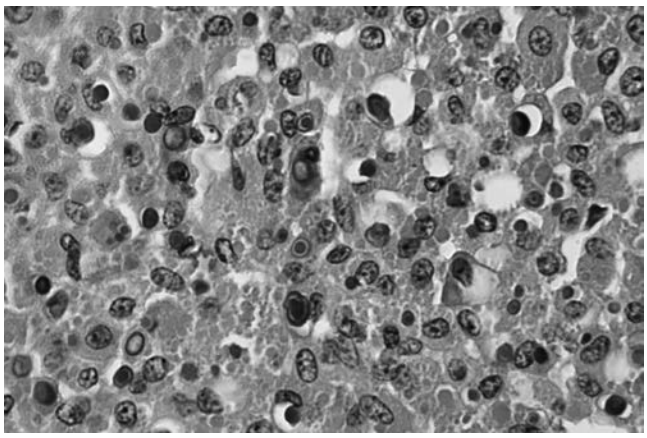

FIGURE 8.19 Malacoplakia. Micrograph demonstrating Michaelis–Gutmann bodies, the pathognomonic finding on microscopy with hematoxylin and eosin (H&E) staining. (Courtesy of WikiMedia Commons, online repository of freely licensed media.)

tongue, gastrointestinal tract, lungs, brain, adrenals, and retroperitoneum, may be involved, but the most common genitourinary site appears to be the kidney.

It has been postulated that the cause is the defective digestion of phagocytosed bacteria due to an intracellular abnormality of macrophage function.[60] Microscopically, malacoplakia consists of large macrophages mixed with lymphocytes and plasma cells. The pathognomonic feature is the rounded intracytoplasmic inclusions, which contain incompletely digested bacterial components mineralized with iron and calcium phosphate salts. These Michaelis–Gutmann bodies are evident on histologic evaluation by their characteristic concentric "owl-eye" appearance (Figure 8.19).

Pediatric genitourinary malacoplakia is quite rare, with very few published case reports in the current pediatric literature. It typically occurs in the setting of recurrent UTIs, usually with *Escherichia coli*.[59] The female-to-male incidence of disease is approximately 4:1. Malacoplakia more often presents in immunocompromised patients, in the setting of renal transplantation, diabetes mellitus, lymphoma, and chronic corticosteroid use, and is often quite resistant to treatment in these populations. Rare case reports document pediatric presentations characterized by symptoms of urinary frequency, dysuria, and recurrent UTIs.[61] Clinically, the lesions of malacoplakia are described as yellowish, polypoid smooth papules, plaques, or nodules with peripheral hyperemia. Draining abscesses and sinus tracts have been reported to occur near the urethra, testes, vulva, and perineum. Renal malacoplakia is suspected in the pediatric patient when response to traditional antimicrobial therapy does not occur. These patients often have persistent nephromegaly without abscesses demonstrated by either ultrasonography or CT. Although renal parenchymal malacoplakia is extremely rare in children, sonography is usually the first imaging modality used for diagnosis of this condition. Sonographic and CT features are generally nonspecific and include circumferential bladder thickening, polypoid bladder

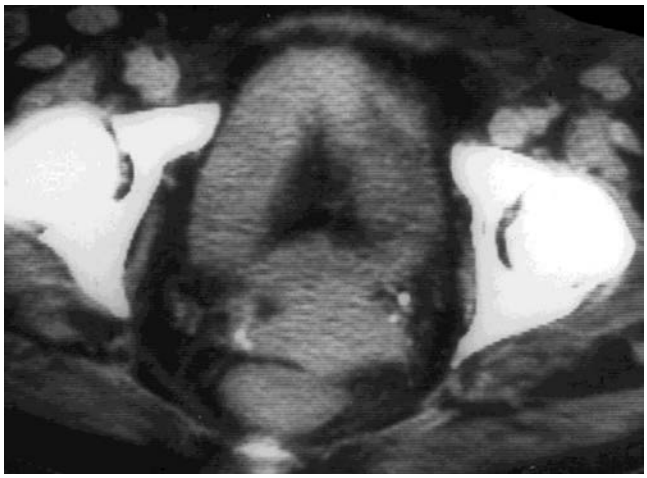

FIGURE 8.20 Malacoplakia. Axial CT demonstrating circumferential bladder wall thickening. (Courtesy of Wong-You-Cheong JJ et al. *Radiographics* 2006;26:1847–68.)

masses, enlarged kidneys, focal hypoechoic masses, and heterogeneous masses with areas of necrosis (Figure 8.20). The renal lesions may be confused with focal nephritis, renal tumors, or lobar nephronia due to these nonspecific features. MRI of renal malacoplakia may show single or multiple nodules with low signal on T1-weighted, T2-weighted, and early and late postgadolinium images.[62] Diagnosis is usually confirmed by renal biopsy (either open or percutaneous), showing chronic parenchymal inflammation with Michaelis–Gutmann bodies. Reports have confirmed the diagnosis by cytologic evaluation of a renal fine-needle aspirate.[63]

Previously, bilateral renal malacoplakia in the pediatric population was considered a fatal disease. Unilateral disease was frequently treated with nephrectomy. Bladder lesions have also been treated with transurethral resection. Patients should receive antimicrobial therapy using an antimicrobial agent with intracellular activity (i.e., trimethoprim-sulfamethoxazole and quinolones), or with immunomodulating pulse therapy with methylprednisolone and intravenous granulocyte colony-stimulating factor (G-CSF). If a patient is on immunosuppressive therapy, a reduction in the immunosuppressive regimen is recommended. With the advent of such treatment, nephrectomy is rarely necessary to treat renal malacoplakia in the pediatric population.

OTHER INFLAMMATORY DISEASES OF THE GENITOURINARY TRACT

Epididymitis, epididymo-orchitis, and orchitis

Epididymitis has been increasingly reported as a cause of acute scrotum in the pediatric population. It results from an inflammatory reaction of the epididymis to an infectious agent, a chemical irritant, or a nonspecific cause. Epididymitis is typically idiopathic, but it can be associated with UTIs, autoimmune disease, trauma, or urinary tract abnormalities (UTAs).[64] Although infection with bacteria or viral organisms is traditionally thought to be the cause of epididymitis, the majority of documented cases are not associated with culture-proven UTIs.[65] Sterile urine in the epididymis may also be sufficient to incite an inflammatory reaction. Epididymal infection may therefore occur as a result of retrograde passage of urine through the ejaculatory ducts, hematogenous spread from a systemic infection, or direct extension from a preexisting orchitis.

Boys with epididymitis usually present with scrotal pain of gradual onset, scrotal erythema, and edema. They are typically exquisitely tender to palpation in the region of the epididymis and the vas deferens. A reactive hydrocele may also be present on exam. The differential diagnosis of epididymitis in a child must always include testicular torsion, torsion of an appendix testis, and idiopathic scrotal edema. A clue to the diagnosis is often the more insidious onset of pain in boys with epididymitis than in boys with torsion events. Careful physical examination and radiologic imaging studies with Doppler ultrasound will often aid in making the correct diagnosis (Figure 8.21).[66] If a definitive diagnosis of epididymitis cannot be arrived at, then surgical exploration may be required to exclude testicular torsion.

The use of a urinalysis in making the diagnosis of epididymitis is often inconclusive. Gislason et al. showed that less than 25% of patients with epididymitis had greater than 10 white blood cells per high-power field on urinalysis at the time of presentation.[67] Graumann et al. studied a cohort of 151 consecutive patients, of which only 1 (1%) demonstrated bacteriuria in his urinalysis.[68] Urinalyses have also been abnormal in 10% of boys that present with testicular torsion. Urine cultures are also unrewarding in making the diagnosis of epididymitis, as only 12% were positive in the cohort of boys with epididymitis that were retrospectively studied by Gislason et al.[67]

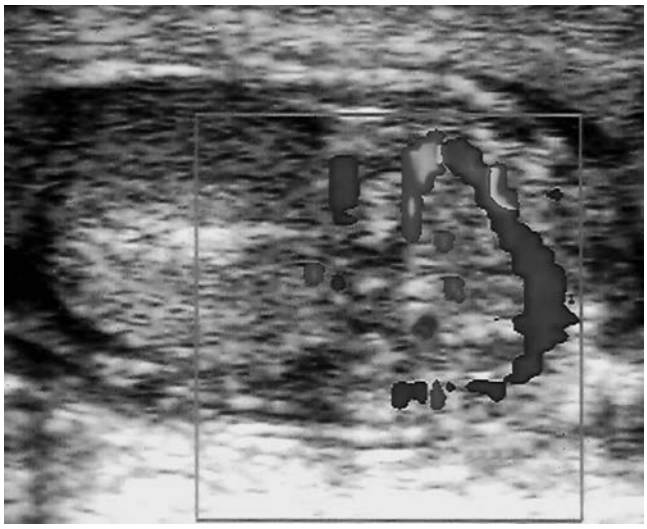

FIGURE 8.21 Acute epididymitis. Ultrasound demonstrating thickened, hyperemic epididymal tail with increased Doppler flow. (Courtesy of Woodward PJ et al. *Radiographics* 2003;23:215–40.)

The evaluation of a boy with epididymitis should not end once the immediate diagnosis has been confirmed. This relatively rare problem in boys is often enigmatic in its etiology. In prepubertal boys, infection in the epididymis may result from a variety of UTAs, such as neurogenic bladder, dysfunctional voiding, urethral obstruction (posterior urethral valves or meatal stenosis), or an ectopic ureter draining into the seminal vesicle or vas deferens.[64] Children with these anomalies more commonly have recurrent or chronic epididymitis, making the recognition of these entities even more important to preventing disease in this population.

Investigational procedures after resolution of the inflammation should be performed. Urologists vary widely in their recommendations for radiologic examinations. Most agree that at a minimum, an upper tract evaluation with a renal bladder ultrasound should be performed for culture-proven bacterial epididymitis. In young children, excretory urography (intravenous pyelography [IVP]) is the imaging study of choice to identify an ectopic ureter draining to the seminal vesicles, while a voiding cystourethrography (VCUG) would demonstrate urethral anomalies and reflux of urine into the ejaculatory ducts (Figure 8.22).[69]

Both neurogenic bladder and dysfunctional voiding have been found to be associated with acute epididymitis. Spasm of the external sphincter is thought to facilitate retrograde urine flow through the vas deferens and ejaculatory ducts. Bukowski et al. found that in a series of 56 boys with epididymitis, nearly 25% had dysfunctional voiding tendencies associated with epididymitis.[70]

Therefore, the addition of a detailed voiding history and use of noninvasive urodynamic testing with uroflow, patch electromyography, and postvoid residual urine assessment have been advocated for boys over the age of 5 years that present with epididymitis. Congenital urologic anomalies are a less frequent cause of epididymitis in the absence of documented bacterial infection.

The treatment of acute epididymitis includes scrotal support and elevation, and analgesic and anti-inflammatory medications. Given the reportedly low incidence of UTIs in boys with epididymitis, antibiotics can be reserved for young infants and those with pyuria or positive urine cultures.[71] Once the acute infection is treated, age-appropriate studies to determine the etiology of the epididymitis should be undertaken.

Vulvovaginitis

Vulvovaginal inflammation is the most common gynecologic complaint of the prepubertal girl. Most cases are initially treated by the primary pediatrician, with subsequent referral to the pediatric urologist or gynecologist only when symptoms persist. Vulvovaginitis is most commonly seen in prepubertal females between the ages of 2 and 7 years. The child is typically brought to the physician with complaints of foul vaginal discharge, discomfort, pruritus, and urinary symptoms such as burning with voiding. The parents may note a discharge present in the child's diaper or undergarments. An abnormal odor and/or redness of the vulva may also be described.

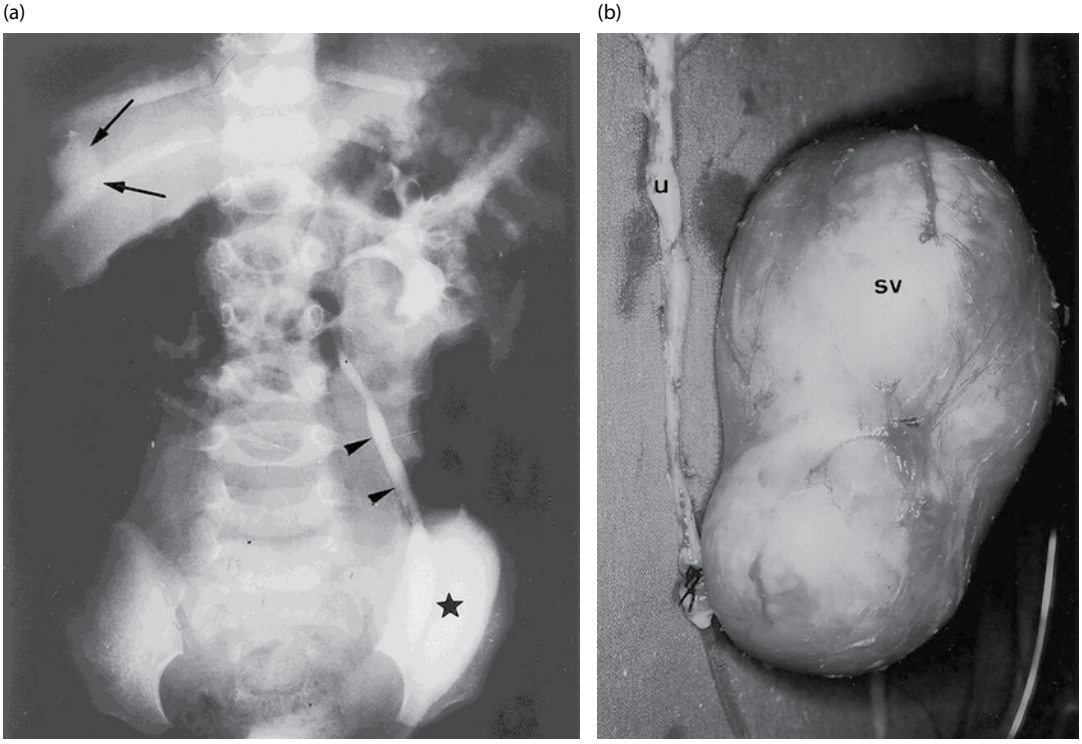

FIGURE 8.22 (a) Intravenous urogram demonstrating left ectopic ureter draining to seminal vesicle and thus displacing the bladder to the left. (b) Gross specimen of ectopic ureter (u) draining to markedly dilated seminal vesicle (sv). (Courtesy of Berrocal T et al. *Radiographics* 2002;22:1139–64.)

Vaginal discharge is physiologic in female neonates. The majority of newborn girls have a clear, white, odorless vaginal discharge during the newborn period that is primarily a response to the perinatal stimulation of circulating maternal estrogens.[72] This should not be mistaken for a pathologic process. At puberty, both the vulvar and vaginal tissues are once again stimulated by circulating estrogens, and therefore swelling and discharge may be expected.

There are several reasons to explain why young girls are particularly susceptible to vulvovaginitis. Anatomically, the vulva of the young girl is relatively unprotected, lacking the natural barrier to infection of the labial fat pads and pubic hair of the postpubertal girl. Vulvar skin is also thin, sensitive, and easily irritated by minor trauma. In addition, the vaginal mucosa is also thin at this age. The vaginal cavity in these prepubertal girls is also an excellent culture medium for bacteria with its neutral pH and warm, moist environment. Finally, the close proximity of the anus allows easy transfer of bowel organisms, particularly in this age group. These obvious structural and biologic differences make the vulvovaginal environment of prepubertal girls particularly sensitive to inflammation. In addition, children tend to have poor hygiene habits compared with adolescents. They do not practice good handwashing and often play in areas that expose them to dirt and sand, creating chronic irritation of the vulva. The presence of a foreign body or suspected sexual abuse must also be considered in the list of risk factors for vulvovaginitis in the prepubertal girl.[73]

In evaluating the young child with vulvovaginitis, the preceding risk factors should be kept in mind. A complete history and detailed perineal examination must be performed. The history should include information concerning the onset of the condition and any therapies previously instituted for treatment. A history of potential chemical irritants should be elicited (i.e., bubble baths, soaps, and powders). A previous surgical history and family history of diabetes, eczema, or contact sensitivities should be addressed. The child's social setting should also be reviewed for information regarding potential child abuse (i.e., primary caregiver, day care, and contact with older children). The physical examination should look for evidence of chronic illness, dermatologic problems, or traumatic injury. Most girls can be comfortably examined either lying supine in their mother's lap or in the frog-leg position. Some sexual abuse experts recommend a knee–chest position for a complete examination. Cultures may be obtained by a sterile saline-moistened swab or a saline flush of the vaginal introitus. If bleeding or malodorous discharge raises the issue of a foreign body, then formal vaginoscopy may need to be undertaken under anesthesia. If a persistent and continuous flow from the vaginal introitus is present, then an ectopic ureter may enter the differential diagnosis. In this situation, ultrasonography or VCUG will assist in confirming the diagnosis.

Malodorous discharge with associated vaginal bleeding should alert the clinician to the possibility of the presence of a foreign body within the vagina. Eighty percent of all foreign bodies present within the vagina are wads of toilet tissue lodged in the vaginal canal.[74] This may result in both an infectious and an inflammatory response. Various other foreign bodies have been recovered, including coins, safety pins, pen tops, and small toys. The probability of foreign bodies being recovered from the vagina of prepubertal girls presenting with vulvovaginitis is 4%.[75] The inflammatory response associated with the presence of the foreign body resolves with the removal of the object.

The treatment of vulvovaginitis depends entirely on the etiology of the inflammation. Nonspecific vaginitis accounts for the majority of these prepubertal cases. It is thought to involve alterations in the normal flora of the vagina, resulting in vulvar and distal vaginal inflammation. The vagina of a prepubertal girl is typically colonized with the same variety of bacteria as observed in older women. A study by Gerstner et al. found that swabs from 75% of these girls grew aerobic bacteria, 65% showed anaerobic bacteria, and 45% grew both. The specific organisms identified were *Staphylococcus epidermis* (35%), enterococci (29%), *Streptococcus viridans* (13%), and lactobacilli (39%).[76] It therefore may be appropriate to request colony counts on all organisms recovered from culture, as overgrowth by one particular organism may warrant antimicrobial therapy directed at that organism. Routine treatment of nonspecific vaginitis is usually directed toward improved hygiene, avoidance of irritating stimuli, treatment of concurrent constipation, and techniques to promote drying of the vulva, such as wearing loose-fitting clothing at night.

Specific vaginitis in prepubertal girls may be the result of infections with *C. albicans* and *E. vermicularis*. Treatments of these infections have been previously outlined in this chapter. Other causes of specific vaginitis include sexually transmitted organisms, resulting in gonorrhea, chlamydia, and herpes. The treatment of these infections is outlined in Table 8.1. These organisms may be acquired during passage of the newborn through the birth canal or may result from sexual abuse. The age at presentation, along with social history and physical examination, will suggest the etiology.

Interstitial Cystitis

Interstitial cystitis is a chronic, debilitating bladder disease of unknown etiology that is seldom reported to occur in children. The first report of the disease was made by Skene in 1878.[77] Since that initial report, there have been only a handful of case reports that document this disease specifically in the pediatric population.

TABLE 8.1 Treatment of specific vulvovaginitis

Specific infection	Treatments
Gonorrhea	Penicillin G, tetracycline, ceftriaxone, cefixime, erythromycin
Chlamydia	Azithromycin, doxycycline, erythromycin
Gardnerella vaginalis	Metronidazole
Herpes	Acyclovir

Patients with interstitial cystitis typically have severe sensory urgency with urinary frequency and bladder pain that may be ameliorated with voiding. Cystoscopy after hydrodistention in these patients will classically show changes varying from petechial hemorrhage to other regions with classic Hunner's ulcers.[78] The majority of patients with interstitial cystitis are middle-aged women. The disease is less frequently reported in men and very rarely documented in children.

Chenoweth and Clawater were the first to report interstitial cystitis in children.[79] In their series of seven cases, they describe the presenting signs and symptoms as diurnal and nocturnal urinary frequency, abdominal pain, and decreased bladder capacity in the context of a negative urinalysis and culture. In addition, these children were described as being extremely anxious and easily upset and having poor appetites. Farkas et al. report that the pediatric cases of interstitial cystitis are more common in adolescent girls.[80]

Close et al. reported the first large retrospective analysis of interstitial cystitis in the pediatric population, distinguishing this disease process with voiding dysfunction.[78] They characterized a cohort of 16 individuals who presented over a 12-year period. Unlike previous pediatric and adult reports, there is less of a female preponderance, with 70% girls and 30% boys in the study population. The most common presenting symptom was urinary frequency and urgency (88%), followed by abdominal pain relieved by voiding (81%). All patients had negative urinalysis and urine culture.

Diagnostic evaluation of pediatric patients suspected of having interstitial cystitis consists of cystoscopy with hydrodistention. Cystoscopically, patients typically have diffuse glomerulations and terminal hematuria after hydrodistention (Figure 8.23). Bladder biopsies, obtained in select cases, classically reveal chronic inflammation with lymphocytic infiltrate. No mast cells or eosinophils are generally noted. Urodynamic evaluation demonstrated early bladder filling sensation with no evidence of involuntary bladder contractions. Bladder capacity is also significantly reduced in these individuals.

Treatment of interstitial cystitis in children is met with the same disappointing results as in adults. Bladder distention may temporarily alleviate symptoms. Repeated hydrodistentions were required by 50% of the patients reported by Close et al.[78] As in the adult population, clorpactin instillations have also been utilized with temporary and often incomplete relief of symptoms. Although intestinal bladder augmentation has been reported as a last-resort treatment option, inflammatory changes consistent with

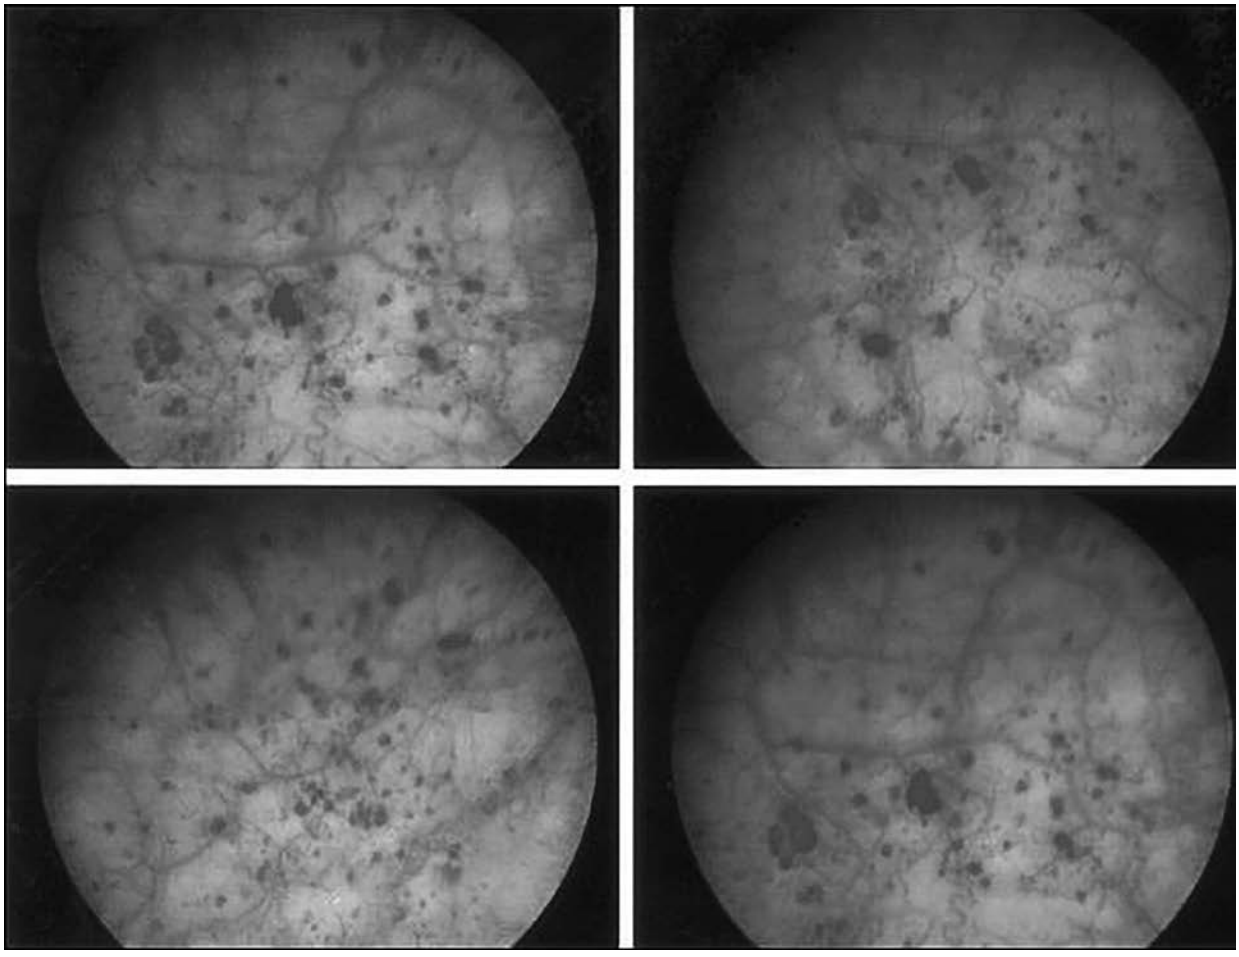

FIGURE 8.23 Interstitial cystitis. Classic appearance of bladder glomerulations after cysto-hydrodistention.

interstitial cystitis have been found in the bowel segments on follow-up. Surgical management of this disease in children should be considered only when all other treatment options have failed and the diagnosis has been absolutely confirmed.

Idiopathic Scrotal and Penile Edema

Acute idiopathic scrotal edema (AISE) is a rare, self-limited clinical entity characterized by genital erythema, edema, and painful scrotal swelling. This is a distinct diagnosis that may be responsible for up to 20% of cases of acute scrotal inflammation.[65] It is important to distinguish this diagnosis from more common causes of acute scrotal swelling, such as testicular torsion, torsion of the appendix testis, epididymo-orchitis, acute hydrocele, or incarcerated inguinal hernia.

The largest single series of idiopathic scrotal edema was reported by Klin et al. in 2002, in which they retrospectively reviewed 38 patients, with 44 episodes of AISE over a 10-year study period.[81] The average age of presentation was 6.2 years (range 2–12 years). Ninety percent of the patients exhibited unilateral involvement, typically with a sudden onset of scrotal erythema and edema, which was minimally tender. Perineal, abdominal, and inguinal extension of the erythema were present in more than 50%.

There has been much speculation as to the etiology of AISE. Suggested etiologies have included infection, insect bites, allergy, mild scrotal trauma, and urinary extravasation. Infection with cellulitis was thought to be the etiology until multiple studies revealed negative intraoperative cultures, no elevation of peripheral white blood cell count, and normal urinalysis and culture.[82] The process is also self-limiting and resolves without the use of antibiotics. Insect bites were also entertained as an etiology; however, the lack of a lesion characteristic of a bite has made this less likely. Allergy has also been suggested as an etiology, especially given the presence of eosinophilia, asthma, eczema, and dermatitis in select cases. In no case, however, has a particular allergen been identified, and the majority of these patients are not characterized as having an allergic diathesis.[83]

AISE typically presents in prepubertal boys between the ages of 5 and 11 years. The children characteristically present with a less than 24-hour history of acute penile and scrotal erythema, edema, swelling, and mild pain (Figure 8.24). Inguinal, perineal, and penile involvement have been reported to occur in up to 60% of cases. The children are frequently afebrile with normal ancillary testing, including urinalysis, and peripheral white blood cell count. Occasionally, eosinophilia is present. When examined early in the process of scrotal swelling, the spermatic cord and testes should feel normal. Characteristically, the clinical findings resolve in 1–2 days. Kaplan reported that in his series of six patients, the examiner had the distinct impression that the edema was confined to the superficial layers of the scrotum, and that it rarely extended to the penis.[83] Lau and Ong reported that a similar benign and self-limiting edematous condition of the penis exists that is suspected to be a variant of idiopathic scrotal edema.[84]

FIGURE 8.24 Acute idiopathic penile and scrotal edema, seen in a 17-year-old boy. (Courtesy of the Pediatric Urology Department of Lucile Packard Children's Hospital, Palo Alto, California.)

If the diagnosis is uncertain, which it often is given the similarity to many emergent causes of acute scrotum, then diagnostic imaging studies may be necessary. Testicular ultrasound is most commonly utilized to differentiate these pathologies. Classic sonographic features include marked thickening of the scrotal wall, with heterogeneous striated and edematous appearance; increased peritesticular blood flow; and at times a mild reactive hydrocele (Figure 8.25).[85]

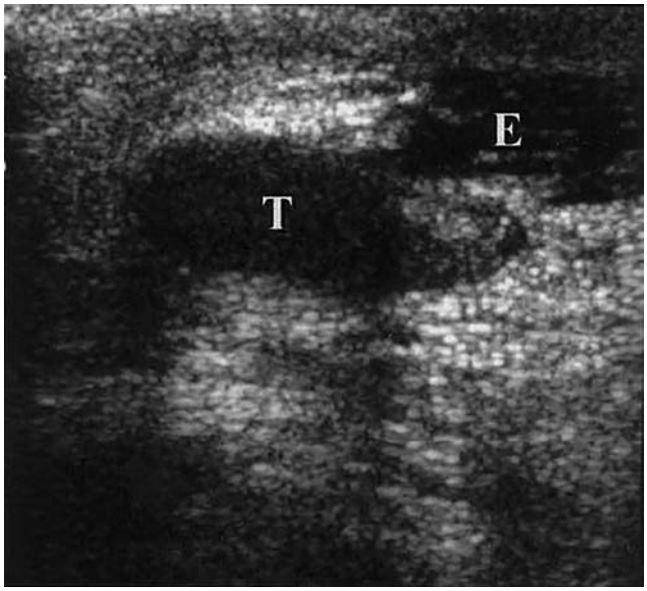

FIGURE 8.25 AISE. Scrotal ultrasound demonstrating markedly thickened scrotal wall with striated, edematous tissue. T, Testis and E, Epididymis. (Courtesy of Klin B et al. *J Pediatr Surg* 2002;37:1200–2.)

Radionuclide testicular scanning or Doppler ultrasonography may be necessary to exclude testicular pathology. On physical examination, this can often be assessed by manipulation of the testis into the superficial inguinal pouch, where it can be noted to be palpably normal and nontender. In rare instances, when diagnostic uncertainty still exists, surgical exploration to rule out testicular pathology will reveal a normal testis and epididymis with inflammation confined to the scrotal wall.

Interestingly, there have been case reports of scrotal edema as a presenting symptom in certain systemic disorders, such as sarcoidosis and inflammatory bowel disease. In Klin et al., sigmoidoscopy was performed to rule out inflammatory bowel disease as the underlying etiology.[81]

Evans and Snyder suggest that idiopathic scrotal edema bears a strong resemblance to angioedema, which is characterized by a localized painless swelling of the subcutaneous tissue of various body parts.[82] The overlying skin is usually normal in color and temperature, but slightly erythematous. Angioedema results from a dilation of small blood vessels, with a transudation of fluid through the capillaries. These vascular changes are believed to be mediated by a local derangement of histamine release. Recommended therapy should consist of reassurance and perhaps a short course of antihistamines.

AISE is nearly always a self-limiting disease. Appropriate management includes reassurance, scrotal support, and close observation. Nonsteroidal anti-inflammatory drugs, antihistamines, or antibiotics may be used as the diagnosis is developed. If the diagnosis is ever in doubt after appropriate clinical, laboratory, and imaging evaluation, then surgical exploration and biopsy may be necessary to rule out nonbenign etiologies.

CHAPTER
9

Anesthesia and Pain Management for the Pediatric Urology Patient

Abraham Rosenbaum, Debra E. Morrison, Shalini Shah, and Zeev N. Kain

CONSIDERING THE WHOLE PATIENT

The pediatric patient who presents for urologic evaluation, consultation, management, and/or surgery should be approached and treated with immense sensitivity. The urologic problem may be just one of a number of associated congenital problems, part of a syndrome, association, or sequence, placing the patient at risk for a series of interventions and/or operations over a lifetime, an ongoing challenge even for a very high-functioning patient. The urological problem may be something incidental to a syndrome, association, or sequence that has other major defining features, or it may be the main feature of the syndrome, association, or sequence. An isolated congenital problem may in itself be associated with the need for serial procedures and/or operations. The urologic problem may be associated with cancer, may be a sequel to another disease process, or may be associated with trauma or a traumatic event, any of which may necessitate serial interventions and exact emotional trauma on a patient and his or her family.

In any case, the urogenital system is both highly personal to each patient and his or her family and immensely essential to both identity and normal physiologic function. Thus, the whole patient and his or her family must be considered, evaluated, and treated appropriately. Any and all events of physiological, physical, psychological, or emotional harm accrue, making life (and medical treatment) more problematic for patients, families, and caregivers. It is essential to minimize unpleasant experiences in order to maximize the incentive to continue necessary follow-up evaluation and management. After all, the patient is the most important member of the medical team and should be cared for as if he or she were a family member and/or a future colleague. Pain, both physical and emotional, should be carefully assessed and addressed during all phases of evaluation and intervention. Awkwardness should be mitigated, as much as possible, by the care team's dignified approach to the patient, who may potentially be embarrassed about being touched, about being different, or having a problem such as incontinence.

PREOPERATIVE EVALUATION

General Diagnostic Principles

1. Individual defects are nonspecific: diagnosis is based on overall pattern.
2. A defect may be isolated but dramatic in its presentation.
3. A defect may be isolated and seemingly minor, but have serious consequences.
4. Expression is variable.
5. Similar phenotypes may result from different etiologies.
6. The earlier the insult, the worse the outcome.
7. Minor anomalies are clues to more serious problems.
8. If there are three or more minor anomalies, evaluate for major malformation, which may be occult.
9. Recessive expression may imply lack of enzyme or metabolic product.
10. Dominant expression may imply faulty structural genes.

General Diagnostic Approach

A patient may present for evaluation for surgery and anesthesia with a urological manifestation of a known diagnosis: one can quickly use a textbook or the Internet to discover any other associated concerns for the surgeon, anesthesiologist, or pediatrician. Some conditions are so rare that discussions of anesthetic and surgical implications have not been published, especially since some conditions have allowed few survivors, but anesthesia concerns can be extrapolated and surmised from descriptions of associated problems.

Alternatively, a patient may present with an isolated routine urological problem but appear to have other anomalous features: note other abnormalities and quickly suggest a diagnosis using a textbook that groups by pattern of defects, or refer to a geneticist when appropriate. An example is a 2-year-old patient who presents for inguinal hernia repair who is noted incidentally to have axillary freckling, an abnormal finding found in several syndromes.

Families or patients may have been given a diagnosis but may not recall it. Perhaps the existence of a name

makes it worse. As time goes on, parents and patients may appreciate having the information, and anesthesiologists certainly will.

Confirming that the urological problem may be part of a larger picture may improve understanding and prediction of prognosis and care in the long term. Associated risks should be detected, such as risk of metabolic problems or latex allergy, presence or risk of renal dysfunction or failure, or presence or risk of other organ dysfunction or failure. Completing the picture may help the physicians, the family, and the patient.

Some syndromes may have other overwhelming features (craniofacial anomalies and cardiac anomalies) that distract other caregivers, patients, and families from the associated urological problems that require intervention and follow-up to prevent complications, such as renal failure.

Tables 9.1 and 9.2 are examples, not comprehensive lists, of urologic diagnoses and associations, syndromes, and sequences.

Specific Considerations

If urologic conditions may be associated with renal insufficiency, baseline renal function should be established. If the patient does have renal insufficiency, or is at risk for developing renal injury, the patient should be evaluated for electrolyte abnormalities, anemia, hypertension, and other metabolic abnormalities that may be associated with his or her overall diagnosis. If hypertension is suspected, care should be taken to measure blood pressure with an appropriate-sized cuff. Renal function and electrolytes should be followed.

Some urologic conditions, such as congenital adrenal hyperplasia, may be associated with endocrine abnormalities and may require careful management and the specific input of the patient's endocrinologist.

Children with congenital urogenital abnormalities or congenital abnormalities that lead to urological problems (neural tube defects, such as myelomeningocele) are at increased risk of developing latex allergy, and exposure should be avoided.

If neuraxial analgesia is considered, make sure the spine is normal. Alternative techniques for postoperative pain management are indicated when spinal anatomy is abnormal.

Antibacterial prophylaxis may be indicated for children with urinary obstruction, urinary infections, congenital heart disease, or other associated problems. Patients with chronic exposure to antibiotics for urological or other indications may already have developed allergies to some antibiotics. Determine what antibiotics are appropriate and order them in advance in order to allow the drug to be given in a timely manner prior to incision by the anesthesiologist. Consider baseline renal function when choosing an antibiotic and the schedule of administration.

TABLE 9.1 Urologic presentations common to multiple associations, syndromes, and sequences

Renal malformation	Genital anomalies
Frequent in	**Frequent in**
Aniridia–Wilms' tumor association Beckwith–Wiedemann syndrome Exstrophy of cloaca sequence Klippel–Feil syndrome Meningomyelocele sequence Oligohydramnios sequence Sirenomelia sequence Tuberous sclerosis VATERR association	Aarskog syndrome Aniridia–Wilms' tumor association CHARGE syndrome Exstrophy of cloaca sequence Noonan syndrome Prader–Willi syndrome
Occasional in	**Occasional in**
Aarskog syndrome Apert syndrome Beckwith–Wiedemann syndrome de Lange syndrome Down syndrome Escobar syndrome Fanconi pancytopenia syndrome Myotonic dystrophy syndrome Prader–Willi syndrome Russell–Silver syndrome Smith–Lemli–Opitz syndrome Treacher Collins syndrome Williams syndrome	Aarskog syndrome CHARGE syndrome Ehlers–Danlos syndrome Fetal hydantoin syndrome Poland sequence Proteus syndrome Russell–Silver syndrome Saethre–Chotzen syndrome Williams syndrome

The Care Team and Safe Induction of Anesthesia

Children who are not able to consent or refuse medical treatment should not be assumed to be cooperative. Safe induction of anesthesia implies not only physiological and anatomical safety, but also emotional safety. Many institutions have policies requiring or restricting parental or family presence during the induction of anesthesia or during minor procedures. We feel this should be an individual decision made considering the patient, the parents or guardians, and anyone else on the care team, including but not necessarily limited to our resident child life staff members, pediatricians, and neonatal intensive care unit (NICU) or pediatric intensive care unit (PICU) physicians, nurses, and respiratory therapists. A nonparental family member who is close to the patient and/or who is a physician might serve as a key member of the care team.

Children may also benefit from a hospital tour, even one that includes a full "rehearsal" of the events that are planned. If diagnostic studies are required prior to an operation or procedure, care should be taken to avoid incurring emotional trauma in the process. Communicate with everyone involved and coordinate the entire experience.

A child and/or a family who suffers emotional trauma while undergoing medical care may carry memories of that trauma forever, affecting all subsequent medical interactions. This affects not only the patient and family, but also subsequent medical caregivers. Avoidance of critical follow-up care is one potential result.

Thus, induction of anesthesia should be planned carefully, with the patient and other involved parties, considering the patient and any past experiences with medical care

TABLE 9.2 Examples of urologic problems, associations, and etiologies

Diagnosis	Urologic	Associated	Mechanism
Aarskog syndrome	Shawl scrotum, phimosis, cryptorchidism, inguinal hernias	Hypertelorism, brachydactyly, short stature, pleasant personality, attention deficit disorder, slightly lower IQ, widow's peak, abnormal teeth, short neck, spina bifida occulta, vertebral abnormalities	X-linked recessive, gene codes for Rho/Rac guanine nucleotide exchange factor, involved in growth regulation and signal transduction
Aniridia–Wilms' tumor association (WAGR syndrome)	Present with hypospadias or cryptorchidism	Moderate to severe mental retardation, prominent lips, micrognathia, ears aniridia ptosis, cataract growth deficiency, microcephaly; look for Wilms' tumor, 1:70 with aniridia	Caused by chromosomal deletion
Apert syndrome	Present with (10%) polycystic kidney hydronephrosis, cryptorchidism, bicornuate uterus, vaginal atresia	Irregular craniosynostosis, midface hypoplasia, syndactyly, broad thumbs, great toes	Autosomal dominant, sporadic, older paternal age: mutations in fibroblast growth factor receptor 2 gene chromosome 10
CHARGE association	Genital hypoplasia in males (75%)	Colobomatous malformation sequence (80%), atresia choanae (58%), growth deficiency, postnatal (87%), mental deficiency (94%), ear anomalies (88%)	Etiology unknown
Exstrophy of bladder sequence	Exstrophy of bladder		Failure of infraumbilical mesenchyme to intercede between bladder portion of cloaca and overlying ectoderm, allowing cloacal membrane to break down, exposing posterior bladder wall (1:30,000, M > F)
Fetal hydantoin syndrome	Renal malformation, hernias, hypospadias, micropenis, ambiguous genitalia cryptorchidism	Growth deficiency, craniofacial abnormalities, hypoplastic phalanges, short neck, rib anomalies, hirsutism, brain anomalies, cardiac anomalies	Dilantin or one of its metabolites; also other anticonvulsants
Russell–Silver syndrome	Posterior urethral valves, hypospadias, renal anomalies, testicular seminoma, Wilms' tumor	Prenatal onset of short stature, skeletal asymmetry, small incurved fifth finger, small triangular facies, small chin, café au lait spots, normal head circumference, sweating and hypoglycemia in infancy, small proportionate adult with normal intelligence (often assumed to be younger than they are); treat with dignity	Etiology unknown, sporadic
Treacher Collins syndrome	Cryptorchidism	Malar hypoplasia, downslanting, palpebral fissures, lower lid defect, ear malformation, cleft palate, scalp hair on lateral cheek, cardiac defects, choanal atresia	Autosomal dominant, 60% fresh mutations, variable, chromosome 5
Urethral stricture	Urethral stricture		Acute or chronic trauma, some unexplained
VATERR association	Renal anomaly (53%)	Vertebral anomalies (70%), ventricular septal defect and other cardiac defects (53%), anal atresia ± fistula (80%), radial dysplasia (65%), single umbilical artery (35%)	Etiology unknown
von Hippel–Lindau syndrome	Renal cysts, pheochromocytoma, renal cell carcinoma, hypernephromata, epididymal cysts	Angiomatous tumor of the central nervous system; hemangiomas of face, adrenal, or lung; liver cysts; cancer of pancreas; cancer of ampulla of Vater; paragangliomas; polycythemia	May have only one lesion, many cases unrecognized, autosomal dominant with variable expression, chromosome 3, altered tumor suppressor gene

or anesthesia. A child's requests, if any, should be honored, if possible, and options, if safe, should be entertained.

Anxiolytics (midazolam) prior to entering the operating room (OR) are fairly routine for children once they begin to experience anxiety with separation from parents. However, some children who undergo repeated procedures grow to dislike the taste of the drug given orally or the symptoms of the drug. Some dislike the taste (even when preflavored) so much that they reflexively wretch; others have been traumatized by the discomfort of nasal administration or the memory of an intramuscular (IM) injection.

Even young patients may request no midazolam, and their requests should be considered.

Parental Absence

Options are whether to take midazolam or whether to have a parent present for induction—neither or either or both. A child life therapist with an exciting iPad app might be more effective than medication for some children. Choices should be offered where they exist, but it should clearly be stated when there are no further options, rather than withholding this truth from a child.

Parental Presence

A 2-year-old patient from the burn unit came down with her mother to the OR for a minor procedure. She had an IV and so was given 0.5 mg IV of midazolam. This had no effect. She continued to cling to her mother and would let no one else near her. More midazolam, up to 2 mg, plus fentanyl, was given, to no significant effect. The anesthesiologist whispered to the nurse, "The bunny suit." The mother was quickly outfitted in a paper coverall, hat, and mask, and assisted into the gurney on her left side with her toddler curled in her arms. The team studiously ignored the mother and child as they were wheeled quietly into the OR. The gurney was parked parallel to the OR table with the child closest to the anesthesiologist who was stationed between the gurney and table, with her head nearest the foot of the table. The pulse oximeter probe and the mask were ready but not yet on the patient. A dose of propofol insufficient to cause apnea was administered. As the child began to relax, the anesthesiologist scooped up the child and spun around, depositing the child on the table as the mother and gurney were quickly wheeled from the room.

INTRAOPERATIVE MANAGEMENT

Safe Airway Management

The position of the patient and where he or she is placed on the table, as well as the length of the case and the need for neuromuscular blockade, will determine, in part, the mode of airway management. A cystoscopy, which might otherwise be brief enough to allow airway management by mask alone, would require at least a laryngeal mask airway (LMA) because the patient must be positioned at the extreme foot of the table. Very small patients can lie across the bed, allowing access to the airway, and may not require more than a mask for a brief cystoscopy.

Another consideration is whether the patient has craniofacial or airway anomalies, making airway management more challenging. A child is not expected to cooperate with awake intubation, and pediatric anesthesiologists have devised methods of managing even the difficult pediatric airway without having to struggle with an awake and uncooperative child.

Vascular Access, Invasive Monitoring, and Fluids

Large operations involving blood loss and fluid shifts may necessitate placement of an arterial line or central line, especially if the child has had a significant number of prior operations, potentially making blood loss more likely and limiting peripheral IV access, and/or the recovery period will be critical or prolonged. It is helpful to anticipate this need and to plan and schedule accordingly.

The use of irrigation or surgical interruption of the urogenital system may make it impossible to utilize urine output to monitor fluid status. The use of irrigation fluid increases the risk of hypothermia via cooling of a body cavity or because the surface on which the body rests becomes damp or saturated. Use warmed irrigation fluid and apply clear plastic sticky drapes at the perimeter of the surgical field before prep to direct fluid, even warmed fluid, which will inevitably cool, away from the body.

Irrigation fluid also makes estimation of blood loss problematic. The amount of irrigation fluid used should be tabulated in order to subtract it from the total volume in the suction container. Large suction systems make estimating blood loss difficult, especially in smaller patients. If there is concern about the potential for blood loss or a patient develops hemodynamic instability possibly attributable to blood loss, and there is no arterial line, hemoglobin may be measured with a small amount of blood from a finger stick or estimated using a noninvasive hemoglobin monitor.

The use of diuretics in certain procedures may also contribute to uncertainty about fluid status, making communication and careful assessment of irrigation, blood loss, fluids administered, insensible fluid losses, and if possible, urine output even more essential.

Medication for Sedation and Anxiolysis

The recommended dose for oral midazolam for sedation and amnesic purposes preoperatively is 0.5–0.7 mg/kg. Children with autism may require doses closer to 1 mg/kg. Many anesthesiologists do not exceed a total dose of 12–20 mg orally. The drug comes premixed with syrup in a 2 mg/mL concentration for oral administration. The 5 mg/mL concentration can also be mixed with syrup. Younger children may be used to taking medication via a syringe; older children may accept the challenge of squirting the syringe quickly by themselves.

When intranasal (IN) midazolam must be given, the dose is 0.3 mg/kg of the 5 mg/mL concentration. This route should only be used in the patient if no other method will be effective, since patients will recall the burning sensation it causes. However, absorption is rapid.

When a larger child is unable to cooperate with either IV placement or induction, IM sedation may be the best choice before induction. Midazolam dose ranges from 0.1 to 0.15 to 0.5 mg/kg, and midazolam may be mixed in the same syringe with a ketamine dose of 1, 2, or 5 mg/kg (with 0.02 mg/kg atropine to prevent hypersalivation caused by ketamine).

If the patient already has an IV, the initial dose for IV midazolam is 0.05–0.1 mg/kg for patients 6 months through 5 years of age, although a total dose of up to 0.6 mg/kg may be necessary in patients who are not naïve to midazolam, and 0.025–0.05 mg/kg for patients 6–12 years of age, although a total dose of up to 0.4 mg/kg may be necessary in patients who are not naïve to midazolam. Patients over 12 years of age should be dosed as adults, with 1–2 mg midazolam.

Choice of Anesthetic Agents

The cooperation of a child should not be taken for granted; thus, general anesthesia should be assumed. The question of whether to place a preinduction IV, if one is not already in place, should be somewhat dependent on the child. A young child with little exposure to anesthesia might find an IV far more threatening than an inhalation induction, but a child with repeated exposures may prefer IV placement over inhalation. Sevoflurane is the least noxious of the volatile anesthetics in use today and is the only volatile agent of choice for induction (halothane is now rarely used). The volatile agents with more noxious odors, isoflurane and especially desflurane, may provoke struggling, salivation, coughing, and laryngospasm, with disastrous results. Nitrous oxide mixed with oxygen is employed briefly at the beginning of induction to provide some sedation before sevoflurane is introduced slowly into the anesthesia circuit to accelerate the speed of induction. In some cases, a rapid induction is achieved by prefilling the circuit with oxygen, nitrous oxide, and 8% sevoflurane. The volatile agent causes peripheral vasodilatation, making it somewhat easier to start an IV, but caution needs to be taken when inducing a child who is hypovolemic or has congenital cardiac anomalies. A high dose of sevoflurane can lead to severe hypotension, bradycardia, and even cardiac arrest during induction. Peripheral dilatation also leads to heat loss—thus the necessity for hot-air warming devices, as well as warmer rooms for smaller patients.

The very youngest patients, those from the NICU, may not tolerate volatile anesthetics, and may instead require high doses of opioids, usually fentanyl, as their agent of choice for general anesthesia. These patients are usually not extubated immediately postoperatively.

Positioning

Positioning requires careful attention, especially in long cases. The head and neck should be in a neutral position, and limbs should be slightly flexed and adducted rather than extended and abducted, in order to prevent traction on tendons and nerves, especially in the high lithotomy position. Arms should be positioned level with or anterior to the midline in the coronal plane to avoid stretching the brachial plexus. In obese patients, who carry an extra-thick "mattress" on their backs, this can be accomplished only by placing extra padding on the arm boards, if utilized, to raise the level of the arms. If arm boards are used, and the table position is other than level, the arms should be secured to keep them from falling off under the drapes. Padding should be used appropriately to prevent pressure injuries. Especially during long cases, the head and limbs not in the surgical field should be moved or repositioned subtly and on a regular basis to avoid prolonged pressure on any single surface, such as the back of the head, or postoperative soreness from maintaining a single position. If the prone position is necessary, care must be taken to avoid pressure on facial structures or the anterior surface of the body. The airway device should be protected, and care should be taken not to rest instruments or hands on the face or to compress the chest. This can be especially challenging in smaller patients.

Antiemetics

While not given routinely in infants and small children, antiemetics may be required in patients who exhibit postoperative nausea and vomiting (PONV). Ondansetron, droperidol, and metoclopromide are and have been used frequently in pediatric patients, although there are many other antiemetics. Ondansetron, one of the most commonly used antiemetics, is a serotonin 5-HT_3 receptor antagonist that affects both peripheral and central nerves, reducing vagal nerve activity, deactivating the vomiting center in the medulla oblongata, and blocking serotonin receptors in the chemoreceptor trigger zone. Other drugs in this class include granisetron, dolasetron, and tropisetron. The clinical effect of drugs of this class can be potentiated by dexamethasone.

Metoclopromide is a nonselective 5-HT_3 receptor agonist.

Droperidol is a butyrophenone and is a D_2 dopamine receptor antagonist with a central antiemetic action. Its antiemetic effect lasts much longer than its sedative effect, so when used, it is given very early in the anesthetic, unlike ondansetron, which must be given close to emergence from anesthesia.

Antiemetic Dosing

Drug	Age/Weight	Dose
Ondansetron IV	1 months–12 years; 40 kg or less	0.1 mg/kg
	>12 years; 40 kg or more	4 mg
Ondansetron ODT oral disintegrating tablet, for nausea and vomiting and no IV	4–11 years; 40 kg or less	4 mg
	>11 years; 40 kg or more	8 mg
Droperidol IV		10 μg/kg every 6 hours
Metoclopromide IV	>14 years	10 mg
	6–14 years	2.5–5 mg
	<6 years	0.1 mg/kg

Principles of Dosing Enteral and Parenteral Drugs

Consider the developmental stage, the weight and body habitus, the history of pain medication use, the degree of tissue damage sustained during the course of the operation, and the setting in which pain medications are prescribed.

Weight might not be proportional to height or length or developmental or chronological age; disproportionate weight can actually reflect a medical or social problem.

All pediatric drug orders and prescriptions should include weight, and for patients well outside the normal in terms of body mass index (BMI), one should consider including BMI as well.

Ideal body weight or lean body weight should be calculated and considered when weight is out of proportion to height and age.

Dosing for pediatric patients who weigh less than 50 kg is in milligrams or micrograms per kilogram.

Dosing for pediatric patients who weigh equal to or more than 50 kg is similar to adult dosing, if BMI is normal.

Calculating a Pediatric Dose Using Ratios

- Dosing for pediatric patients in the 50–70 kg range can be better determined by using a ratio to determine the dose per kilogram: 1/70 kg × Adult dose (in units/kg) = Dose in units/kg.
- Thus, for an acetaminophen dose of 1000 mg every 6 hours for an adult, 1/70 × 1000 mg = 14.3 mg/kg and 14.3 mg/kg × 55 kg, and so, more conservatively, a 786 mg acetaminophen dose would be for a 55 kg patient.

Older children and adolescents who are developmentally appropriate can tolerate patient-controlled analgesia (PCA), but PCA by proxy for younger children is not recommended, with exceptions. Some parents become very experienced in helping to manage their child's pain.

Drugs should be "layered" as pain management is escalated, starting with nonopiates, such as local anesthetics (a temporary solution for immediately postoperatively), acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs) (if not contraindicated), and sometimes gabapentin, if a patient can tolerate oral medication. These drugs should be continued even when opiates and ketamine are added during necessary escalation of pain management.

Assessing Pain in Children

Evaluation of pain in children is problematic, especially when children are not able to use words.

Infants have no verbal skills and are entirely dependent on the clinician or parent for pain assessment. Signs of pain may include disturbances in eating and/or sleeping; rigid posture, including bringing the knees up to the chest; crying and other vocalizations signaling distress; and facial expressions.

Toddlers may have minimal vocal skills. Even when they are able to report the presence of pain, they are unable to describe it (this may persist into adult life in some people). They are vulnerable to secondary gains (attention, treats, and new toys). They also have trouble understanding cause and effect. Toddlers may also exhibit, as signs of pain, disturbances in eating and/or sleeping, guarding or thrashing about, crying and other vocalizations signaling distress, regression to more immature behavior, and clinginess to parent or other caregiver. Facial expressions may also give evidence of pain.

School-aged children are able to verbalize pain and can be more descriptive. They may also be vulnerable to secondary gains (watching television, missing school, treats, and gifts) and may exaggerate their pain. They may exhibit as signs of pain, stiffness, or rigidity, as well as eating or sleep disturbances. Facial expressions are also a key to the level of pain.

Pain assessment is thus age dependent, but the patient should be questioned to the limit of his or her ability to respond. A pain rating scale, using either faces or numbers, can be utilized. Observe behavior and physiological signs. Enlist the family and listen to their assessment, since they know their child's baseline. Consider the cause of the pain. Treat and continue to assess the effectiveness of the treatment.

PAIN MANAGEMENT

Escalating Pain Management

1. Local anesthetics and nonopioid adjuvants include aspirin, acetaminophen, NSAID, gabapentin, and clonidine.
2. Add an opioid for mild to moderate pain: codeine (if effective) or hydrocodone (*stop* plain acetaminophen, aspirin, or NSAID if prescribing combination drugs).
3. Add an opioid for moderate to severe pain: morphine, oxycodone, hydrocodone, fentanyl, methadone, or ketamine.

Use noncombination drugs in order to prevent confusion leading to acetaminophen toxicity. If using a combination drug, make it very clear that either acetaminophen *or* the combination drug may be used.

Start with low doses and titrate upward, but be aggressive about managing pain.

Medication for Pain Management

Opioids

Opioids are central-acting analgesics used to treat moderate to severe pain. Administration can be oral, nasal (given as a small dose just prior to the end of a short outpatient procedure to treat immediate pain and ease emergence from anesthesia), parenteral, neuraxial (spinal or epidural), or transdermal (fentanyl patch, usually prescribed for palliative pain). Parenteral opiates are usually prescribed for acute moderate to severe postoperative pain. Oral opioids are available as elixirs or pills or tablets, and as single drugs or in combination with acetaminophen, aspirin, or NSAIDs, and are usually prescribed for acute mild to moderate postoperative pain or as soon as a patient is able to tolerate oral medication.

Morphine, a natural derivative of opium, has been in use for more than 150 years. Substituted semisynthetic

(oxycodone and hydrocodone) and complex synthetic (meperidine, fentanyl, and methadone) opioids are widely used to treat moderate to severe pain.

Morphine, which has a half-life of 3 hours, is the basic unit of comparison with other opioids; 1 mg of morphine is equivalent to 0.2 mg of hydromorphone, 50 μg of fentanyl, and 10 mg of meperidine.

Opioids bind to binding sites for endogenous substances, such as endorphins and enkephalins, which modulate the transmission and perception of pain because they are structurally and chemically similar. Although opioids reduce or eliminate the suffering from pain, they do not, unlike local anesthetics, ablate the perceived location of the pain. Unlike local anesthetics, they do not affect the sensation of light touch, pressure, and temperature.

Four Opioid Receptor Subtypes

- Mu, or opioid receptor subtype 1, mediates supraspinal analgesia, respiratory depression, nausea and vomiting, miosis, bowel hypermotility, euphoria, physical and psychological dependence, and increased release of prolactin and growth hormone. Mu receptors are widely studied.
- Kappa, or opioid receptor subtype 2, mediates spinal and visceral analgesia, as well as sedation, but seems not to have much of an effect on respiration. There are peripheral kappa receptors found in the gastrointestinal tract, skin, muscle, and connective tissue, providing analgesic, antineuropathic, and anti-inflammatory effects. Kappa receptors in the kidney are associated with antidiuresis and oliguria.
- Delta, or opioid receptor subtype 3, seems to enhance, facilitate, or modulate the effects of mu and kappa receptors.
- Sigma-1 receptors, no longer considered true opioid receptors because they are not affected by opioid antagonists, are believed to mediate opioid-associated dysphoria, hallucinations, and confusion.

It was long assumed that individual responses to opioids were similar. However, opioid receptor pharmacogenomic research has revealed genetic variants in receptors and other genes involved in responses to opioids. Patients differ in their responses to different opiates. While it is presently impractical to pretest patients in order to prescribe opiates effectively, it becomes evident which drugs are effective in a given patient.

While patients should be on a regular pain regimen, doses for breakthrough pain should always be available.

Drug doses for the treatment of opioid side effects should be calculated in advance.

Listen to the patient and their families when they describe side effects and intolerance associated with specific opioids and not with others. Many times, physicians erroneously interpret this behavior as "drug seeking." These patients and families have observed the effects of their genetic uniqueness in their responses to given drugs. Some drugs do cause dysphoria, hallucinations, or severe itching and may not treat pain effectively in given patients. An overly sedated patient can still be in pain but be unable to communicate this.

Parenteral Opioids

Parenteral Opioid Doses

Drug	Dose <50 kg	Dose >50 kg
Morphine	Bolus 0.1–0.3 mg/kg every 2–4 hours	Bolus 5–8 mg every 2–4 hours
	Infusion 0.2–0.3 mg/kg/hour	Infusion 1.5 mg/hour
Fentanyl	Bolus 0.5–1.0 μg/kg every 1–2 hours	Bolus 25–50 μg every 1–2 hours
	Infusion 0.5–2.0 μg/kg/hour	Infusion 25–100 μg/hour
Hydromorphone	Bolus 0.01–0.02 mg/kg every 2–4 hours	Bolus 1 mg every 2–4 hours
	Infusion 0.006 mg/kg/hour	Infusion 0.3 mg/hour

Patient-Controlled Analgesia

Components of a PCA include drug choice (usually morphine, fentanyl, or hydromorphone), loading dose, PCA bolus dose, basal rate (if any), lockout time, and maximum hourly dose.

Morphine is often the default drug for PCA. The loading dose should average about 100 μg/kg. The bolus dose should start at 0.03 mg/kg. The basal rate (if any) should average about 0.03 mg/kg/hour, with a 6- to 10-minute lockout time. The maximum hourly dose should be about 20 μg/kg. If pain is not controlled, the bolus dose should be increased by 10%–20%. Other maneuvers are to increase the basal rate infusion (if any) by 20%–40%, decrease the lockout time, and make sure the patient is not consistently reaching the hourly maximum dose. It may be necessary to switch to another opioid if morphine is ineffective.

If the patient is experiencing side effects, treat the treatable side effects individually (itching, nausea and vomiting, and constipation) or switch opioids, often necessary when side effects include hallucinations or dysphoria.

Oral Opioids

For children too young to swallow pills, but who are able to swallow a liquid, an elixir is an excellent choice, although not all pharmacies can supply liquid opiates. Options are morphine regular release in various concentrations, hydromorphone, codeine alone and in combination with acetaminophen in various strengths (the dose of acetaminophen stays the same), hydrocodone in combination with acetaminophen, methadone, oxycodone, and oxycodone in combination with acetaminophen. When pain is expected to be somewhat short term, oxycodone can be given around the clock. When pain is expected to be more long term, oxycodone HCl CR (OxyContin) or MS Contin can be prescribed. Older children, who are able to swallow pills, can be prescribed opioids in tablet form.

Drug	Dose <50 kg	Dose >50 kg
Codeine	0.5–1 mg/kg every 3–4 hours	30–60 mg every 3–4 hours
Morphine	Immediate release	Immediate release
	0.3 mg/kg every 3–4 hours	15–30 mg every 3–4 hours
		Sustained release
		30–45 mg every 3–4 hours
Oxycodone	0.1–0.2 mg/kg every 3–4 hours	5–10 mg every 3–4 hours
Methadone	0.1 mg/kg every 4–8 hours	10 mg every 4–8 hours
Hydromorphone	0.04–0.08 mg every 3–4 hours	2–4 mg every 3–4 hours

Oral Opioid Doses

Codeine is a weak opiate with many side effects, including nausea and vomiting, and is not considered a first-line treatment for pediatric patients. Codeine becomes effective after being metabolized to its active metabolite morphine by cytochrome P-450 in the liver. Many people (including people of Asian, Arab, and African American descent) are unable to metabolize codeine; thus, they cannot benefit from the drug. On the other hand, 0.5%–2% of patients are extensive metabolizers, which can lead to a more pronounced than expected effect from codeine, potentially leading to overdose. On August 15, 2012, the Food and Drug Administration (FDA) warned physicians and caregivers about the risks of giving codeine to children, especially those with sleep apnea, because of the variable rate in which individuals metabolize codeine, placing some children at risk of overdose. A further bulletin was released by the FDA on February 20, 2013.

Transitioning from Parenteral to Oral Opioids

When a patient who has been on parenteral opioids needs to be transitioned to an oral equivalent, an equianalgesic oral dose of the drug that has been effective for the patient should be determined, as a starting dose. When it is necessary to switch drugs, as would be the case for a patient who was on fentanyl, use an IV dose of the new drug equivalent to that of the previous drug (Table 9.3), and use the parenteral–oral ratio to determine the dose of the oral drug. Thus, 100 μg IV of fentanyl is equivalent to 2 mg IV of morphine, so an oral dose of morphine would be 6 mg.

Acetaminophen

Acetaminophen is the most commonly prescribed nonopioid analgesic. The mechanism of action is the central inhibition of cyclooxygenase. The drug causes no adverse effects on gastrointestinal motility, renal function, or platelet function. It is available for oral, rectal, and IV administration.

Doses for neonates and infants are best determined by a pediatric specialist. However, children over 6 months to 2 years can tolerate a rectal dose of 90–120 mg/24 hours, divided to allow q4–q6 hour dosing intervals or an oral dose of 90 mg/kg/day, again divided to allow q4–q6 hour dosing intervals.

Children 2–12 years can tolerate a rectal loading dose of 40 mg/kg, followed by rectal doses of 20 mg/kg every 6 hours. Oral doses in this age group are 10–15 mg/kg every 6 hours.

The IV dose for children of 2–12 years and <50 kg who are unable to take either oral or rectal acetaminophen, given as an infusion over 15 minutes, is 15 mg/kg every 6 hours, with a maximum dose of 75 mg/kg/24 hours. For children of >50 kg, the dose is 1000 mg every 6 hours, given as an infusion over 15 minutes, with a maximum dose of 1000 mg/24 hours. In the 50–65 kg range, however, consider continuing weight-based dosing, which gives a lower dose.

Nonsteroidal Anti-Inflammatory Drugs

The mechanism of action of NSAIDs involves the inhibition of cyclooxygenase in the periphery. NSAIDs are a useful adjunct to opioid therapy in the acute pain setting, when not contraindicated by unacceptable side effects. Prolonged use is not recommended.

Ibuprofen is the most commonly used oral NSAID for outpatient pediatric pain relief, and it can be used in alternating fashion, every 6 hours, with acetaminophen *or* a combination oral drug containing acetaminophen and an opioid, such that the patient receives one drug every 3 hours, immediately postoperatively. The dose is 10 mg/kg in patients ages 2–12 who are <50 kg.

As pain diminishes, the ibuprofen should be discontinued first, followed by the opioid, in favor of plain acetaminophen as necessary.

Ketorolac may be given, if desired, as one IV dose immediately postoperatively, at a dose of 0.5 mg/kg, with a maximum dose of 15–30 mg.

TABLE 9.3 Parenteral to oral

Drug	Parenteral dose	Oral dose	Parenteral: Oral ratio
Morphine	10 mg	30 mg (long term)	1:3
Fentanyl	100 μg	No oral equivalent	N/A
Hydromorphone	1.5–2 mg	6–8 mg	1:4
Methadone	10 mg	10–20 mg	1:2

Abbreviation: N/A, not applicable.

Adjunct Pain Medications

Adjunct pain medications include gabapentin (40 mg/kg/day given in divided doses three times per day), indicated when pain is more chronic in nature. Ketamine has been used in chronic pain management, especially in patients who are tolerant to opioids, but should be prescribed, after evaluation, by a specialist in pediatric pain management.

Local Anesthetic Agents

The mechanism of action of local anesthetics is reversible inhibition of the conduction of neural impulses along central and peripheral nerve pathways. To be effective, local anesthetics must be manually deposited in the immediate vicinity of the nerves to be blocked, and therefore are virtually unlike any other class of anesthetic or analgesic medication. Duration of action is determined by washout by local blood supply, resulting in spontaneous recovery of nerve function without evidence of any structural detriment to the nerve tissue.

For decades, children were considered poor candidates for local anesthetic techniques not only because of their fear and distress of needles, but also because of the resultant pain caused after injection of local anesthesia. Children were thus unable to benefit from regional anesthetic techniques in the management of procedural and postprocedural pain. There was the added assumption that children did not "feel pain," which is evidenced by the fact that until 1980, children were not given intraoperative opioids and were given very little anesthetic for surgery. Local anesthesia can provide complete anesthesia in situations where general anesthesia is neither practical nor possible, such as in newborn circumcision and management of postprocedural pain.

In brief, local anesthetics inhibit sodium (Na+) conductance during an action potential. During an action potential, voltage-gated Na+ channels open briefly, allowing extracellular Na+ to enter the cell. This phenomenon is called depolarization of the plasma membrane. Local anesthetic molecules block neural conductance in peripheral, spinal, and cortical axons by inhibiting Na+ from entering or by interfering with conformational changes that allow the channel to depolarize. Again, local anesthetics do not alter the resting potential of the membrane; they block sodium permeability at specific ion-gated sodium channels and *slow* the rate of depolarization so that an action potential is inhibited.

The minimal concentration of local anesthetic necessary to block impulse conduction along a given nerve is called the Cm. Factors that affect the Cm include fiber size, myelination of nerve, pH, local calcium concentration, and the rate at which an action potential along a given nerve is transmitted. Each local anesthetic has a unique Cm, which reflects the differing potencies of each drug. For example, unmyelinated fibers (C and Ad) have a lower Cm than heavily myelinated fibers (AB). Because of the lower Cm, less local anesthetic is needed in dose and volume to block nociceptive transmission than to block muscle contraction or motor conduction.

The choice of which local anesthetic agent is suitable depends on multiple factors, primarily the type of blockade needed (analgesia vs. anesthesia), route administered (subcutaneous, peripheral nerve block, epidural or caudal, or spinal), onset time, duration of action, and presence of patient comorbidities (i.e., decreased hepatic function). Where and *how* neural block is performed determines the decision concerning which local anesthetic to use. For example, some local anesthetics cannot be used intrathecally (chloroprocaine). Otherwise, in most clinical situations, the choice of local anesthetic is determined by duration of action, and very infrequently by onset of action, as long-term postoperative analgesia is the ultimate goal.

Types of Local Anesthetics

Local anesthetics all contain a lipophilic aromatic ring, a hydrophilic tertiary amine, and an ester or amide linkage between the aromatic ring and the tertiary amine. Thus, local anesthetics are all classified as either "amide" or "ester" based on the type of linkage. All amide local anesthetic names contain the letter i in the first part of the word (excluding the "caine," which all share).

Amides and Esters

Amides	Prilocaine Lidocaine Ropivacaine Bupivacaine Levobupivacaine
Esters	Tetracaine Benzocaine Cetacaine

Chemical groups attached to the aromatic ring have an influence on the speed of onset, while groups attached to the tertiary amine have an influence on anesthetic potency and lipid or aqueous solubility. Epinephrine mixed with local anesthetic (lidocaine and bupivacaine), when not contraindicated, prolongs duration by vasoconstriction and decreased blood flow.

Typical Applications of Local Anesthetics

Topical Tetracaine can be used on the eye. Cetacaine can be used on nasal, oral, and laryngeal mucosa. Prilocaine can be used on the skin, whether intact or damaged. Lidocaine can be used in the urethra.	**Neuraxial** Bupivacaine can be used for intrathecal, caudal, or epidural (single shot or continuous). Tetracaine can be used for spinal. Lidocaine can be used for epidural. Ropivacaine can be used for caudal or epidural. Levobupivacaine can be used for caudal or epidural.
Infiltration Lidocaine, ropivacaine, bupivacaine, and levobupivacaine can all be used for field blocks or specific nerve blocks (brachial plexus, ankle, intrabulbar, retrobulbar, dental, etc.).	**Miscellaneous** Bupivacaine can be used for trigger point injections. Lidocaine alone can be used for IV regional (Bier) block; it is also used to treat chronic regional pain syndrome.

Regional and Neuraxial Techniques

Generally, regional anesthesia is used when systemic therapeutics are expected to or have failed to provide adequate analgesia, or when adverse effects from opioids are excessive, or when the initial surgical or postsurgical insult will be too great and there is anticipation that IV or enteral routes of administration of analgesics will be ineffective. Advantages also include possible blockade of transition from acute pain to chronic, persistent pain states in children, in which the pain has considerable adverse influence on the child's daily functions and prevents the child from participating in his or her normal roles, irrespective of the child's coping ability.

In the past, the main challenge was in identification of pain, and adequate pain assessment in neonates, infants, and small children. Over time, the issue has advanced to which pharmacologic agents would be appropriate for this age group, at which dose, and how to minimize toxicity. Expectations from parents have also evolved; a high degree of comfort and pain relief is now expected. All attempts are made to apply best evidence-based clinical practices to the use of regional and neuraxial anesthesia and analgesia in children; however, there are often no prospective, randomized double-blinded controlled trials of regional anesthesia in the pediatric population. As a result, most data that guide therapy are extrapolations from the adult literature, where possible.

The basic requisites for safe and effective regional and neuraxial anesthesia include selection of the best strategies for postoperative analgesia. This begins with an evaluation for expected anatomical location of pain, duration of analgesia required, expected intensity of postoperative pain, and surgical technique. Within these contexts, there is considerable influence on the anesthesiologist's decision regarding type of regional blockade.

In most surgical procedures, a single-shot nerve block (whether peripheral or caudal) is appropriate in terms of duration of anesthesia and associated morbidity outcomes. Moreover, most single-shot nerve blocks are appropriate for outpatient surgical procedures. As a general rule, motor block is generally very poorly tolerated by neonates and infants and should be avoided when at all possible. Discharge from the recovery room is generally not precluded by persistent sensory block; however, motor block may delay discharge in order to monitor for compartment syndrome. If motor block is suspected, likely culprits include postlumbar plexus block or ilioinguinal nerve block performed where the motor branch of the femoral nerve may be blocked. If long-lasting analgesia is required, particularly after extensive surgical reconstruction, a postsurgical epidural or caudal catheter can be placed for infusion of continuous local anesthetic and/or opioids. Ideally, since the child is still under general anesthesia during the placement of the neuraxial block, signs and symptoms of local anesthetic toxicity or total spinal anesthesia may be masked, and therefore a greater margin of safety is required for placement. In these scenarios, placement with fluoroscopic guidance, nerve stimulation-guided technique, or ultrasound guidance technique is highly recommended to guide visualization of the needle and minimize complications of the regional block, as well as in those patients at risk for compartment syndrome (i.e., those who will require plaster casts postoperatively).

The caudal block is one of the most frequently applied techniques to access the epidural space in pediatric patients. It is particularly useful for achieving excellent sensory analgesia after urological procedures, and can be used as the sole anesthetic when required. Briefly, the patient can be positioned in the prone or in the lateral decubitus position. The border of the caudal canal is the line intersecting the two sacral cornua superiorly and the sacral hiatus inferiorly (triangle formation). The needle is inserted at the top of the gluteal fold in the sacral hiatus and advanced until the sacrococcygeal ligament is punctured. A loss of resistance will be noted, suggesting puncturing of the sacrococcygeal ligament. Once through the ligament, the needle is then flattened and advanced 1–2 mm. Local anesthetic is then deposited after confirmed negative aspiration for heme or cerebrospinal fluid (CSF) and after a negative test dose.

COMPLICATIONS OF ANESTHESIA AND PAIN MANAGEMENT

Side Effects and Complications of Opioids

Continued exposure to opioids leads to the development of tolerance and physical dependence or addiction.

Tolerance is the progressive increase in dose required to maintain the same desired pharmacological effect.

Physical dependence is normal and commonly observed in opioid-tolerant patients. Parasympathetic tone is increased when opioids are discontinued abruptly and patients experience symptoms of withdrawal: sweating, shaking, cramping, and diarrhea.

Psychological dependence includes drug-seeking behavior and use of drugs for purposes other than pain control.

While patients suffering moderate to severe acute pain may experience physical dependence on opioids, they do not often experience psychological dependence.

Addiction is the term used to describe an extreme form of psychological dependence where patients experience craving and impaired control with compulsive use despite incurring harm. This behavior is reinforced by physical dependence and fear of withdrawal.

Opioid-induced hyperalgesia (OIH) occurs in patients who have developed tolerance to opioids, but has been observed in patients newly exposed to rapid-acting short-duration opioids, such as remifentanil and alfentanil. OIH is characterized by hyperesthesia (paradoxical increases in the intensity of pain), allodynia (changes in the characteristics of the pain), and new pain complaints in response to continuous administration or increased dosing of opioid analgesics.

Other undesirable side effects include respiratory depression, bradycardia, constipation, urinary retention, pruritis, oversedation, hallucinations, delirium, and nausea and vomiting.

Narcotic Antagonists

Naloxone is used to treat opioid-related respiratory depression. The standard dose is 10 μg/kg IV push every 3 minutes

in patients of <40 kg. However, this dose, equivalent to the standard adult dose of 0.4 mg or 400 μg, should not necessarily be given at once unless the situation is dire and opioid overdose is massive. In the case of massive overdose, with apnea, naloxone up to 50–100 μg/kg can be given to patients of <40 kg and up to 2–4 mg in patients of 40 kg or greater. Doses of this magnitude are rarely required.

Positive pressure ventilation should be initiated immediately, after which 1–2 μg/kg IV push should be given, and then repeated every 3 minutes. A patient of <40 kg who requires more than 2 μg/kg or a patient of 40 kg or greater who requires more than 0.08 mg or 80 μg will really need to be intubated and remain intubated until the excess narcotic, which has a longer half-life than naloxone, wears off, in order to avoid another event.

Diphenhydramine is used to treat opioid-associated pruritis. The standard dose is 5 mg/kg/24 hours, given every 6–8 hours—thus 1.25 mg/kg every 6 hours or 1.67 mg/kg every 8 hours in patients of >1 year of age.

Stool softeners are recommended to prevent and treat opioid-related constipation.

Acetaminophen Toxicity

Metabolism of acetaminophen is hepatic, via three pathways: conjugation with sulfate, conjugation with glucuronide, or metabolism via the cytochrome P-450 oxidase enzyme system. Ninety percent of the metabolism of an ingested dose is by conjugation, but the approximately 5% via the P-450 system produces N-acetyl-p-benzoquinone imine (NAPQI), which is directly hepatotoxic. Reduced glutathione, an antioxidant compound in the liver, renders NAPQI harmless, and NAPQI-reduced glutathione is then excreted by the kidneys.

In the case of acute or chronic acetaminophen overdose, the sulfation and glucuronidation pathways become saturated and the amount and rate of formation of NAPQI are greatly increased, depleting reduced glutathione stores, allowing NAPQI to bind to hepatocytes, causing cell death.

Symptoms are nonspecific, and include nausea and vomiting. Laboratory evidence of liver damage will not be immediately evident. Elevated serum levels of acetaminophen can predict toxicity, however, if the timing of acute ingestion is known, but are not predictive after chronic, repeated ingestion.

The antidote for acetaminophen poisoning is N-acetylcysteine, which works to prevent or limit liver damage if toxicity is detected and treated in time.

Side Effects and Complications of NSAIDs

Side effects and complications include coagulopathy, gastrointestinal bleeding, bruising, bleeding at the site of the wound, renal injury, bronchospasm, and bone marrow suppression. NSAIDs should not be combined with aspirin.

Side Effects, Complications, and Cautions for Antiemetics

Ondansetron side effects, complications, and cautions: Hypotension, headache, constipation, elevated liver function tests (LFTs), and short-lasting QT prolongation. Metabolism is by liver and kidneys; hepatic oxidative metabolism accounts for more than 95% of clearance from the body. Clearance decreases and half-life increases in patients with severe hepatic insufficiency.

Ondansetron ODT: To be opened immediately prior to use by peeling the foil blister backing completely off the blister rather than pushing it through the foil, and then placed on the tongue and allowed to disintegrate, after which it should be swallowed with saliva. Note that this tablet contains <0.03 mg of phenylalanine.

Droperidol side effects, complications, and cautions: Sedation, dizziness, anxiety, hypotension, QT prolongation, extrapyramidal symptoms (EPSs), and torsades de pointes (high doses). The drug contains a black box warning, necessitating a specific hospital policy for use. Monitor with electrocardiogram (EKG) for 2–3 hours.

Metoclopromide side effects, complications, and cautions: Drowsiness, diarrhea, and EPSs. Metoclopromide is excreted principally through the kidneys; thus, in those patients with a creatinine clearance below 40 mL/min, the dose should be halved. The drug undergoes minimal hepatic metabolism and is safe in patients with hepatic insufficiency.

Treatment of EPSs: EPSs are various movement disorders; usually in the context of droperidol or metoclopromide, acute dystonic reactions, caused by the blockade of dopamine receptors in the basal ganglia. Patients may exhibit stiffness or tremor, and muscle spasms of the face, tongue, or jaw: an "angry" facial grimace, torticollis, and oculogyric crisis. An observer might describe the child as angry and uncooperative. The first-line of treatment is diphenhydramine, which also has antiemetic and sedative effects. The pediatric dose is 2–5 mg/kg for patients of <12.5 kg and 25–50 mg for patients of >12.5 kg.

Complications of Local Anesthetics

Major local anesthetics complications can be categorized as allergic and toxic. Although rare, local anesthetic toxicity can be dangerous and potentially fatal. The danger of toxic blood levels has been well recognized since the introduction of cocaine, and although techniques of regional anesthesia have evolved, local anesthetic toxicity is still a major concern.

Allergic Reaction to Local Anesthetics

It is quite common for patients to describe an allergy to local anesthetics. However, upon careful history taking, most reactions are determined to be either syncope or vagal reaction in nature, often as a response to the needle injection, or palpitations as the result of epinephrine absorption.

True allergic reaction can occur as a result of the following three components of local anesthetics: the ester or amide group itself, the preservative sometimes used in multiple dose vials (methylparaben), or the antioxidant used in some formulations. The antioxidants (sodium bisulfite and metabisulfite) are usually used with products that contain vasoconstrictors to prevent biodegradation by oxygen. The ester group of local anesthetics is associated with a higher

incidence of allergic reaction due to its para-amino benzoic acid (PABA) metabolite. Allergic reaction to amide local anesthetics is very rare. Cross-sensitivity between ester and amide local anesthetics is extremely uncommon.

A hypersensitivity reaction is more challenging to diagnose when a patient is under general anesthesia. Self-limiting skin manifestations, urticaria, pruritus, and facial edema are the most common reactions without any further sequelae and can be treated with histamine H1 antagonists. In many cases, no treatment is needed. Bronchodilators may be required if the cutaneous reaction is followed by pulmonary bronchoconstriction.

Anaphylactic shock, characterized by hemodynamic collapse, is a life-threatening reaction that can be fatal if not treated. The anaphylactic response is mediated by a Type I hypersensitivity reaction in which immunoglobulin E (IgE) antibodies react with the allergen. In response, vasoactive mediators, histamine, leukotrienes, basophil kallikrein (BK-A), and platelet-activating factor are released into the bloodstream. The hemodynamic response occurs because of both systemic vasodilatation and increased capillary permeability. Bronchoconstriction and mucosal edema of the lower airways and swelling and angioedema of the upper airways are typical. Under endotracheal anesthesia, in addition to tachycardia and severe hypotension, an abrupt dramatic decrease in end-tidal CO_2, as a result of a decrease in cardiac output and pulmonary perfusion, is a major finding that strongly supports the diagnosis.

Anaphylactoid reaction, as the name implies, resembles anaphylaxis but is not IgE mediated and does not require prior introduction of the antibody. The reaction occurs as a result of mast cell activation by a particular drug. As a result, histamine release and complement activation occur. Distinguishing between anaphylaxis and anaphylactoid reaction is difficult and has no importance during the acute phase, since both reactions are treated in a similar way. Tryptase will usually be elevated in anaphylactic but not in anaphylactoid reaction.

The treatment in the OR starts with administration of 100% oxygen, 20 mL/kg IV fluid bolus, and discontinuation of the offending drug. The epinephrine dose is determined by the severity of the reaction, but usually 0.01 mg/kg IV epinephrine (maximum single dose of 0.1 mg) is needed and can be repeated every 5–10 minutes. Some authors advocate the administration of 0.05 mg/kg IM of epinephrine in addition to the IV dose in order to maintain a sustained blood level. A continuous epinephrine infusion may be needed as well, depending on the severity of the response.

Other drugs recommended during anaphylactic shock are an H1 blocker (diphenhydramine, 1 mg/kg IV up to 50 mg, or aminophylline, 5–6 mg/kg IV over 30 minutes), an H2 blocker (ranitidine, 1 mg/kg IV up to 50 mg, or famotidine, 0.5 mg/kg IV for children 1 year old or older), and steroids (methylprednisolone, 1–2 mg/kg IV, or hydrocortisone, 1 mg/kg IV).

Local Anesthetic Toxicity

Local anesthetic toxicity occurs as a result of a systemic overdose that can result in central nervous system and hemodynamic insult or hematologic consequences (methemoglobinemia).

Local anesthetic toxicity is a dose-dependent complication and can occur as a result of continuous absorption of the drug from the interstitial space after regional nerve block or from an inadvertent IV injection, even if the dose given is less than or equal to the maximum recommended dose. Toxicity depends on many variables, such as total dose of injection, rate of uptake, technique of administration, protein binding, lipid solubility, acid–base status, liver and renal function, and vascularity of the injection area (intercostal > caudal > epidural > brachial plexus > sciatic or femoral).

For regional anesthesia, the maximum recommended dose of lidocaine for infants and neonates is 7 mg/kg with epinephrine and 5 mg/kg without epinephrine.

The maximum recommended dose of bupivacaine is 1.5–2.0 mg/kg for neonates and 2.5 mg/kg for infants. An easy approximation for bupivacaine is 1 mL/kg of 0.25%, reduced by one-third for infants younger than 6 months of age.

Adding epinephrine to bupivacaine makes only a small change in the maximum recommended dose but is helpful for the diagnosis of inadvertent IV test dose injection.

A stereoselectivity of bupivacaine has been reported. The R(+) isomer blocks sodium channels more rapidly and more strongly than the R(−) isomer. This phenomenon can explain the greater cardiac toxicity of bupivacaine compared with that of ropivacaine.

Special attention and care should be taken when local anesthetics are administered to a severely ill child who has congestive heart failure or hepatic insufficiency. The dose should be calculated according to lean body weight rather than actual weight.

If a larger volume of local anesthetic is required, a lower concentration should be used.

The mechanism of action of local anesthetics is by blockade of sodium channels and limiting the initial upstroke of the action potential and its propagation. In addition, bupivacaine inhibits outflux of the potassium current, which results in prolongation of the action potential.

The classic description of local anesthetic toxicity is that of an exaggerated propagation of symptoms, both neurological and cardiovascular. Neurological symptoms are initial excitation that progresses to central nervous system depression. The patient who is old enough to describe symptoms initially describes tinnitus, metallic taste, tingling, dizziness, confusion, dysphoria, and numbness around the mouth. If not treated, these symptoms progress to agitation, motor twitching, seizures, loss of consciousness, coma, and respiratory arrest. Seizure is the most common symptom of local anesthetic toxicity and occurs 68% of the time.

Cardiovascular symptoms start with a short phase of hypertension and tachycardia that progresses to ventricular ectopy, ST changes, change in T wave configuration, dyspnea, QRS widening, hypotension, ventricular tachycardia, ventricular fibrillation, bradycardia, and asystole.

While the first symptoms of lidocaine toxicity are neurological, followed by cardiovascular symptoms if the dose and rate are high enough, the neurological symptoms of bupivacaine toxicity are followed immediately or appear simultaneously with cardiovascular symptoms. The lack of neurological prodrome plus the longer half-life

of bupivacaine explains the higher likelihood of adverse outcome with bupivacaine toxicity.

In neonates and infants, early signs of toxicity may be easily missed or misdiagnosed as inappropriate pain relief. Local anesthetic toxicity is even more challenging to diagnose in the anesthetized child. Thus, occurrences of any problems or symptoms after local anesthetic administration or infusion should always raise the question of toxicity.

Treatment of Local Anesthetic Toxicity

Local anesthetic injection should be stopped and help should be summoned immediately.

Local anesthetic toxicity treatment can be divided into supportive and definitive types.

Supportive Treatment

The airway should be secured and maintained, preferably with an endotracheal tube. Administration of 100% oxygen and hyperventilation to increase plasma pH is warranted. Seizure control can be achieved with benzodiazepines or propofol in small incremental doses. In case of circulatory arrest, cardiopulmonary resuscitation should be started using standard protocols. Arrhythmias should be managed per the same pediatric advanced life support (PALS) protocol, recognizing that arrhythmias may be refractory to treatment. Cardiopulmonary bypass should be considered. If circulatory arrest does not present, conventional therapies may be used to treat hypotension, bradycardia, or tachyarrhythmia. Most cases can be resolved with supportive measures only.

Definitive Treatment

In case of severe toxicity, IV lipid emulsion should be initiated (propofol is not a suitable substitute for lipid emulsion). The initial dose of IV 20% lipid emulsion, 1.5 mL/kg, should be administered promptly. (This means that IV lipid emulsion should be immediately available when local anesthetics are administered.) Thereafter, a continuous infusion of 20% lipid emulsion at 15 mL/kg/hour should be initiated.

However, if cardiovascular stability has not been restored after the initial bolus of lipid, up to three repeated lipid emulsion boluses every 5 minutes are required. The infusion dose can be increased to 30 mL/kg/hour if cardiovascular stability has not been restored. (The authors' experience suggests that giving too much is less risky than not giving enough.) Neonates and infants may require higher bolus doses up to 3 mL/kg. Chest compressions should be continuously performed if a nonviable cardiac rhythm exists until resolution of dysrhythmias with effective cardiac output.

There is laboratory evidence that epinephrine and vasopressin may impair resuscitation during local anesthetic toxicity. Therefore, epinephrine should be used in low doses for treating hypotension if it is refractory to other measures, and lipid emulsion should be initiated as soon as possible during resuscitation in cases of severe toxicity.

Risk Reduction

Use the lowest dose of local anesthetic. Always consider comorbidities, metabolic status, and medications used by the patient (sodium channel inhibitors), and reduce the local anesthetic dose accordingly. Consider the use of intravascular markers (epinephrine mixed with local anesthetic will cause tachycardia, indicating that the local anesthetic has also entered the bloodstream) and a test dose. Aspirate prior to each injection while observing for blood. Inject by smaller incremental doses. Continue to be alert for local anesthetic toxicity, as local anesthetic can continue to be absorbed from the site of injection.

Methemoglobinemia

Oxidation of ferrous [Fe^{2+}] iron to ferric iron [Fe^{3+}] results in methemoglobin. Methemoglobin has a decreased ability to bind oxygen and a greater affinity to bound oxygen, which shifts the hemoglobin dissociation curve to the left. Symptoms of methemoglobinemia are proportional to methemoglobin concentration and are limited to skin and blood color appearance when the concentration is less than 15%. When the methemoglobin concentration exceeds 15%, neurologic and cardiac symptoms occur due to cellular hypoxemia. A methemoglobin level of more than 70% is fatal.

During normal physiologic conditions, when the methemoglobin level is less than 1%, methemoglobin is converted back to its ferrous state by nicotinamide adenine dinucleotide (NADH) cytochrome b_5 reductase. This system is overwhelmed when there is an excess level of methemoglobin and hypoxemia results.

Two-wave pulse oximetry shows an oxygen saturation (SpO_2) of 85% since the methemoglobin absorption ratio for 660–940 nm wavelengths is 1. Diagnosis can be confirmed with a multiple-wavelength co-oximeter. Classically, the blood color is described as chocolate brown.

Local anesthetics known to induce methemoglobinemia when used in excess are prilocaine (used topically as EMLA cream), lidocaine, benzocaine (hurricane spray), and bupivacaine. It is easier to reach toxic levels in children because of their low body weight.

The maximum recommended pediatric dose for prilocaine is 2.5 mg/kg.

The maximum EMLA application area for neonates of <3 months is 10 cm^2; for infants of 3–12 months, 20 cm^2; for 1- to 6-year-olds, 100 cm^2; and for 7- to 12-year-olds, 200 cm^2. However, a patient's weight may not always be proportional to his or her age, and this must be considered in determining the maximum dose for an individual patient.

The maximum application time is 4 hours, except for neonates, where the application time should not exceed 1 hour.

Treatment of Methemoglobinemia

Treatment is based on oxygen supplementation and methylene blue. The dose for 1% methylene blue solution is 1–2 mg/kg intravenously over 5 minutes. This dose can be repeated in 30–60 minutes depending on clinical response. Treatment with methylene blue uses an existing minor metabolic pathway, the nicotinamide adenine dinucleotide phosphate (NADPH)–methemoglobin reductase system, to convert methemoglobin back to hemoglobin.

Methylene blue cannot be used to treat methemoglobinemia in patients with glucose-6-phosphate dehydrogenase (G-6PD) deficiency because G-6PD is needed in the conversion pathway. Symptomatic methemoglobinemia

can be treated in these patients with exchange transfusion. Hyperbaric oxygen has also been used.

CHAPTER
10

Office Pediatric Urology

Patrick C. Cartwright, Siam Oottamasathien, and Brent W. Snow

INTRODUCTION

The environment of a medical office can play a pivotal role in making pediatric patients and their families comfortable. Engaging decorations, bright colors, toys, and play areas often help calm nervous children. A bulletin board with patient photos and cards may soften the feel of the office. Every effort should be made to allow parents to be with their child at all times to provide reassurance. Each physician's style and personality is different, but often those who deal with children usually forgo the formality of a white coat so that the encounter might be more familiar to the patient. It is important upon entering the examination room to first engage the patient in gentle conversation, when possible, to develop rapport and place the child at ease. If the child is old enough, history taking generally begins with the child and is supplemented by parental input.

The physical examination is generally performed on the examining table with a parent standing beside the physician at the head of the bed. It is important to let the child know that he or she will not be poked or hurt but gently checked. As children approach puberty, they may be relieved to have one or both of their parents leave for the examination when given this opportunity by the physician. After the exam is completed, it is generally important to let the patient know that he or she is finished so that he or she will no longer be ill at ease. Upon leaving the office, children are often rewarded for their good behavior so they will look forward to return visits.

Most physicians find that dealing with children in an honest, straightforward manner is best. It is appropriate to tell the child before any uncomfortable or painful procedures are undertaken so that he or she will not fear the entire time, but only the first few moments that it occurs. Surprising a child with an unpleasant exam or injection results in a loss of trust and faith in the physician, which is difficult to regain. Parents are encouraged to tell their children honestly about diagnostic x-ray examinations and office visits so that the children can be appropriately prepared. Under these circumstances, the exam and history may be completed accurately with little threat to the child.

FORESKIN AND PHIMOSIS

The appropriate management of penile problems in childhood is based on an understanding of genital embryology and postnatal penile development. Genital differentiation takes place between the 9th and 13th weeks of gestation. The glans penis forms from the genital tubercle and is covered with a prepuce that is adherent to its surface. The preputial attachments persist throughout gestation, and the epithelial layer of the inner prepuce and the glans penis are fused at birth. The newborn foreskin cannot be retracted without disrupting this natural adherence. Subsequently, glandular secretions and desquamated epithelial debris, collectively called smegma, collect between the inner prepuce and the glans penis, gradually separating these two layers. The buildup of this material can be impressive, and patients may present with a mass that can be seen through the thin foreskin. This has been referred to as a foreskin pearl. Treatment is not required, as the smegma eventually erupts at the foreskin meatus, disrupting the adherence and resulting in partial separation of the foreskin.[1] This sequence is often misdiagnosed as a penile infection, and the smegma is presumed to be "pus." Hopefully, physicians easily recognize that this is not an infection but the physiologic appearance of smegma. Reassurance usually quiets parental concerns.

The physiologic adherence (physiologic phimosis) resolves spontaneously, but may remain present for several years. Texts suggest that most physiologic phimosis resolves by the age of 3–5 years, such that the glans penis can be fully exposed.[2] In the authors' experience, limited adherence is of little significance and may remain for years longer. In a longitudinal study, Oster[3] reported that physiologic phimosis in school-aged boys resolved over time (Table 10.1).

Physiological phimosis should be distinguished from pathologic or true phimosis. Physiologic phimosis exists when the adherence between the inner prepuce and glans penis persists as filmy attachments (Figure 10.1). True phimosis occurs when the foreskin cannot be retracted after it has been previously retractable, if there is a densely thickened prepuce that will not retract, or when foreskin

TABLE 10.1 Incidence of phimosis in children

Age (Years)	Phimosis (%)	Tight Prepuce (%)
6–7	8	1
8–9	6	2
10–11	6	2
12–13	3	3
14–15	1	1
16–17	1	1

FIGURE 10.1 Physiologic phimosis. This prepuce displays normal healthy-appearing circumferential tissue, with no evidence of scar or contracture.

remains nonretractile after a patient has completed pubertal development.

The easiest way to differentiate physiologic phimosis from pathologic phimosis is careful examination. Forceful separation of foreskin adhesions is not recommended because of pain and trauma to the patient, but gentle proximal traction of the foreskin may enable one to differentiate between normal and abnormal. If the foreskin retracts part way and then lies flat against the glans penis and effaces or thins, the remaining attachments are likely physiologic and more time is required for natural separation to occur. If, when the foreskin is retracted to the point of attachment, a thickened, rolled edge is seen, then this is likely pathologic phimosis due to scarring and inflammation (Figure 10.2). Ballooning of the foreskin during voiding is often associated with true phimosis as well. Phimosis is unlikely to resolve on its own and may require circumcision. There have been recent studies suggesting that steroids applied to the prepuce and glans penis will help separate physiologic adhesions, aiding in the resolution of this diagnostic dilemma.[4–7]

Questions often arise about care of the uncircumcised penis. The genital area should be cleaned as any other skin area, and the foreskin may gently be retracted to the extent allowable without discomfort for cleaning. Forcible retraction may result in tearing of the foreskin meatus, inflammation, and secondary scarring leading to true phimosis.

POSTCIRCUMCISION PHIMOSIS (ENTRAPPED PENIS)

Following routine neonatal circumcision with any standard circumcision clamp, an unusual type of secondary phimosis can develop. Since the circumcision scar is circumferential, and the process of wound healing involves contracture, this may cause narrowing of the shaft skin at the circumcision site. If the circumcision site is mobile and sufficient inner foreskin remains, the circumcision site can migrate distally over the glans and begin to contract in this position (Figure 10.3). This contraction and scarring may

FIGURE 10.2 This prepuce displays a true 'phimotic ring' laterally and inferiorly with thickened skin, whereas superiorly the skin shows a more normal, effaced (thin) appearance when the foreskin is pushed gently toward the base of the penis.

be tight enough that the glans penis can no longer be seen and occasionally urinary flow may be restricted. This type of phimosis (penile entrapment, secondary phimosis) can be avoided by firmly seating the bell of the newborn clamp at the coronal margin so that there is not redundant inner prepuce remaining, which might let the circumcision scar ride distally over the coronal margin. This seems to be a more common problem in young boys with an abundant pubic fat pad who may not be candidates for circumcision in the first place (Figure 10.4). If secondary phimosis is discovered early after circumcision, aggressive foreskin retraction by stretching the ring with a hemostat dilates the scar and the need for later revision of the circumcision is avoided. In other cases, the phimotic ring may be anesthetized and snipped in the office, incising vertically and closing horizontally to create a wider circumference. This may not resolve the problem in all patients, and formal circumcision revision may be necessary in some, reducing the inner foreskin length so that the circumcision scar cannot migrate past the coronal margin; occasionally, removal of more shaft skin becomes necessary. Some authors have reported the use of topical steroid cream for the treatment of postcircumcision phimosis, yielding complete resolution in a majority of patients.[8]

FIGURE 10.3 Entrapped penis following circumcision (secondary phimosis).

FIGURE 10.4 Severe penile entrapment. This required incision of the phimotic ring in two locations followed by horizontal closure of the vertical incision lines.

PENILE GLANULAR ADHESIONS (SKIN BRIDGES)

After newborn circumcision, the glans epithelium is denuded owing to separation of the physiologic adhesions with the foreskin. The circumcision site is also a raw surface, and if the glans epithelium and the circumcision site rest together for a prolonged period, a postsurgical adhesion may form (Figure 10.5). These are dense adhesions that cannot be teased apart in the office. These adhesions usually occur as skin bridges so that an instrument tip can be passed underneath them, and their blood supply comes from both the shaft skin and the glans. Surgical division of such skin bridges is required.

This usually requires some sort of analgesic agent, which may be EMLA® cream (2.5% prilocaine and 2.5% lidocaine; Astra Pharmaceuticals, Westboro, Massachusetts), or local injection in the office, or if more extensive, general anesthesia. After appropriate analgesia, a hemostat is used to crush the bridge near the glans and the adhesion is divided with scissors, rotating the blade and cutting the skin bridge nearly flush with the glans epithelium. Sometimes a second cut flush with the shaft skin will be necessary for good cosmesis. It is important not to cut the skin bridge in the middle because this often leaves a skin tag of shaft skin on the glans penis, which is a noticeable cosmetic problem. Suturing may be necessary for bleeding or wound approximation. Ointment is then placed on the penis twice daily for 7–10 days; gently retracting the shaft skin prevents the two edges from coming into contact to reform the adhesion.

PARAPHIMOSIS

Paraphimosis is the term applied when the foreskin that has been retracted cannot then be brought back over the glans penis (Figure 10.6). This can happen after the foreskin has been forcefully separated for the first time, disrupting the preputial adherence to the glans. In the hospital, this often occurs when the foreskin has been retracted for the placement of an indwelling catheter. Once the catheter has been secured, medical personnel neglect to replace the foreskin over the glans penis. With the tight foreskin proximal to the glans penis, venous congestion leads to progressive swelling. When paraphimosis is recognized, it is imperative that the foreskin be immediately placed back over the glans to allow the blood flow to return to the prepuce and glans. If there is significant edema, this can be difficult. The best technique

FIGURE 10.5 Postcircumcision skin bridges.

is to hold a gauze sponge with the index and third fingers of each hand proximal to the foreskin, with the gauze covering the fingers for traction. The thumbs push the glans penis back through the paraphimotic ring between the other four fingers that are supporting it. A minute or two of steady pressure may be required to decompress the glans and force the foreskin edema proximally and allow for the glans to suddenly slip through to the paraphimotic ring. Placing ice on the penis before this procedure has been advocated, and a penile anesthetic block may be administered before the manual reduction. Additionally, infiltration of the edematous foreskin with hyaluronidase has been reported to facilitate decompression via dispersing extracellular edema, thus permitting easy reduction of the foreskin.[9] Briefly, approximately 1 mL of hyaluronidase (150 U/cc available as Wydase; Wyeth-Ayerst Laboratories, Philadelphia, Pennsylvania) is injected into several sites in the edematous prepuce using a fine-gauge (≤27 g) syringe followed by gentle, circumferential pressure. The edema will resolve almost instantaneously such that the paraphimosis can be reduced.

Some authors have also reported the use of granulated sugar as an effective and safe technique to reduce paraphimotic foreskin edema.[10] If manual reduction is unsuccessful, immediate dorsal slit of the tight preputial ring will restore venous drainage from the distal tissue. A formal circumcision can be completed at a later date if necessary.

FIGURE 10.6 Paraphimosis with edematous, discolored prepuce trapped proximal to glans penis.

MEATAL STENOSIS

Stenosis of the urethral meatus seems to be largely an acquired problem of circumcised boys. Recurrent meatitis or meatal inflammation secondary to prolonged exposure of the meatus to the moist and irritating environment of the diaper (ammoniacal dermatitis) or other inflammatory skin diseases can induce this problem. The delicate meatal skin edges lose their superficial epithelial lining when inflamed, and as a result become adherent in a side-to-side fashion. This almost always occurs ventrally and progresses dorsally, and boys are left with a small or even pinpoint meatus at the apex of the glans. Some authors have suggested that the advent of disposable diapers has led to an increasing prevalence of this problem since the 1980s. The occurrence of meatal stenosis is distinctly unusual in an uncircumcised boy, and therefore is best considered a potential side effect of circumcision.

Causes beyond simple irritation that can induce strictures of the meatus include prior hypospadias repair or other penile surgery, prolonged urethral catheterization, trauma, or balanitis xerotica obliterans (BXO). These diagnoses are often apparent on examination or when reviewing the child's history. BXO induces a characteristic whitish circumferential discoloration of much of the glans and may induce a narrowing of the urethra extending more proximal than simple irritative meatal stenosis. BXO is more difficult to treat.

Normal meatal caliber based on age has been reported in boys. In general, a boy under the age of 1 year should have a meatus that easily accepts a 5-French feeding tube. Between the ages of 1 and 6 years, this increases to at least an 8-French size. It can be difficult to estimate meatal size accurately when inspecting this visually. However, gentle lateral traction on the meatal edges to open the meatus side to side reveals the typical fused appearance of the ventral edges, confirming some degree of stenosis. On the other hand, if normal urethral mucosa can be everted, meatal size is probably accurate. Final confirmation is obtained by observing voiding. There is a characteristic dorsal deflection of the stream due to a ventral lip of scar tissue as a result of fusion of the meatal edges. The patient also demonstrates a very fine-caliber, forceful stream with a long voiding distance. This is due to the acute decrease in the size of the lumen of the urethra distally and the secondary accelerated velocity of the urine. Some patients

FIGURE 10.7 Vertical incision for meatotomy following 60 seconds of clamping with a hemostat.

will learn to direct their penis toward their feet during voiding so that the stream will enter the toilet bowl, while others seem not to catch on and miss the bowl entirely.

Meatal stenosis is uncommonly diagnosed prior to a boy becoming toilet trained. There may be intermittent dysuria with discomfort at the tip of the glans and occasional blood spotting in the underwear due to recurrent inflammation at the meatus. Patients with meatal stenosis demonstrate a prolonged voiding time, and some boys decide that it is simpler to sit during voiding rather than try to direct their streams while standing. It should be noted that meatal stenosis is an unlikely cause of recurring urinary tract infection (UTI) or true obstruction to the lower urinary tract. When the history, exam, and observation of the urinary stream suggest meatal stenosis, no other diagnostic evaluation is required.

When any of the above symptoms are present, and voiding is characteristic, treatment of meatal stenosis is generally warranted. Simple dilatation of the urethral meatus will often result in tearing of the skin edges and a high rate of recurrent stenosis. Urethral meatotomy is therefore the preferred method of treatment. Meatotomy is a very simple procedure in which one prong of a hemostat is inserted within the urethral meatus and directed toward the ventrum in the midline of the glans a few millimeters proximal to the stenotic pinpoint meatus. The skin edges are crushed together for 1–2 minutes. Once the clamp is removed, fine scissors are used to incise the ventral midline, thus reopening the meatus (Figure 10.7). The crushed skin remains together, generating appropriate hemostasis.

Options exist in terms of anesthetic techniques for meatotomy. The procedure may be performed under a general anesthetic in the operating room as a quick and simple outpatient procedure; however, this is generally not necessary. Some urologists have performed this procedure in an office setting by injecting a small amount of lidocaine with epinephrine directly into the ventral meatal skin using a small-caliber needle. This provides analgesia and hemostasis. However, most boys will not tolerate this since the injection is distinctly uncomfortable.

The authors have reported using topical EMLA cream (eutectic mixture of local anesthetics) applied over the entire glans to anesthetize the meatus and perimeatal skin for urethral meatotomy.[11,12] Others have recently reported a similar use for EMLA cream.[13] The EMLA cream is applied liberally over the entire glans, especially on the ventrum. It is secured in place with an occlusive dressing and left in contact with the glans skin for 1–1.5 hours before the procedure (Figure 10.8). The cream is removed and the meatotomy is completed. The vast majority of patients experience no discomfort when EMLA cream

FIGURE 10.8 EMLA cream is applied over entire glans prior to meatotomy. This remains for at least 60 minutes before the procedure.

is used with this technique. Occasionally, there will be a sensation of pressure when the hemostat is clamped. This is almost always at the most proximal point of clamping. In an occasional patient, the EMLA cream may be supplemented with a small amount of injected lidocaine with epinephrine, which seems to be minimally uncomfortable when given following EMLA. Uncommonly, a patient may require a suture on each side of the meatotomy for oozing from the meatal edges following the procedure.

Patient tolerance of the procedure overall is quite good as long as a caring and patient approach is taken to reassure boys before and during the procedure. The room is quiet with minimal lighting, and parents bring some of the child's books and handheld toys for the waiting period after the EMLA is applied. Parents stay in the room during the procedure, and this further reassures the child. The authors have chosen, based on parental preference and patient personality, to use midazolam hydrochloride as an anxiolytic with good results in some patients. However, the general observation has been that midazolam is unnecessary for the majority of patients.

Following meatotomy, it is crucial to keep the edges of the meatus separated so that restenosis does not occur. Immediately following meatotomy, while still in the office, the parent is shown how to apply antibiotic ointment within the meatus. The parent then continues this at home, using one hand to separate the meatus, while the index finger of the other hand is used to place a small amount of ointment directly into the meatus. This is continued twice daily for the first 2 weeks and then once daily for another 4 weeks. Alternatively, a small tube of ophthalmic ointment (Lacri-Lube) may be used as a meatal dilator. A small amount of the ointment is extruded from the metal tip for lubrication, and the tip is then passed within the meatus. It is of appropriate size to serve as a dilator for most boys undergoing meatotomy. The use of meatal dilation may be helpful in certain cases if readherence of meatal edges is problematic, but the authors do not feel that it is routinely required.

Patients may be expected to experience mild dysuria for the first 1–2 days postoperatively. It has generally been helpful to have them take ibuprofen or acetaminophen 2 hours preoperatively to decrease discomfort. Boys at the age of 3 or 4 years may respond to meatotomy by holding the urine for prolonged periods of time. Placing them in a warm tub often stimulates voiding in this circumstance. One value of keeping ointment over the meatal edges is that it functions as a barrier to shield the surface from the passage of urine and the resulting discomfort. It should also be noted that increasing the fluid intake for the first day or two following the procedure dilutes the urine and leads to less dysuria. Minor blood spotting in the underwear following meatotomy is common for 1–2 days. Printed handouts are given to parents with these recommendations, and they are warned of the risk for restenosis when the instructions are not followed. In addition, boys who remain wet following meatotomy, from either still being in a diaper or having problems with persistent incontinence, are at risk for redeveloping stenosis based on recurrent inflammation of the meatus. This group may not be candidates for treatment until dryness is achieved. Two out of 226 patients seen by the authors required a second meatotomy. Over the same period that they have used EMLA cream for analgesia, the authors have chosen to perform meatotomy in the operating room in three boys due to patient behavioral issues, including extreme attention deficient disorder. As experience has been gained, it has become apparent that midazolam works well in the moderately, overactive, anxious, or difficult young boy, and meatotomy in the operating room should be reserved for the patient with BXO of posthypospadias meatal stenosis.

NONNEONATAL CIRCUMCISION

The pros and cons of newborn circumcision have been and will continue to be debated. Less discussion surrounds circumcision after the newborn period, when it is estimated that 1 in 100 uncircumcised boys will require circumcision.[14] During childhood, the most common indication for circumcision is phimosis. This develops because of preputial irritation leading to inflammation, scarring, and thickening of the preputial opening so that the foreskin cannot retract. Hygiene then becomes a problem, and occasionally, this process is so severe that urine flow is affected and the preputial sac dilates with urine dribbling out after voiding. In some patients with chronic skin irritation and inflammation, fissures of the prepuce develop. This makes spontaneous erections and retraction of the foreskin painful, and discomfort occasionally awakens the patient during sleep. Steroid ointments may reduce inflammation, but circumcision is indicated if fissures persist.

Balanoposthitis is an infection of the glans and preputial sac. This infection occurs uncommonly, but can be painful. Skin floras are usually the predominant organisms found on culture. If the balanoposthitis is mild, sitz baths and topical antibiotic ointment (bacitracin) may be sufficient. If cellulitis and/or fever are present, then a systemic antibiotic is added. The first episode of balanoposthitis is not a mandatory indication for circumcision. Recurrent episodes strengthen the argument for circumcision. Penile hygiene should be reviewed with the parents and patient.

UTIs are more common in uncircumcised boys, especially during the first 6 months of life.[15] Some consider a UTI in a boy an indication for circumcision. After 1 year of age, the increased risk for UTI in the uncircumcised male diminishes.

Penile cancer is known to be prevented by newborn circumcision. It is thought that the development of penile cancer closely correlates with penile hygiene, and in developed countries where hygiene is good, the rate of penile cancer is very low regardless of circumcision status. Since penile cancer is very uncommon, the likelihood of a serious circumcision complication may be higher than the eventual possibility of penile cancer.

Occasionally, trauma to the prepuce leads to circumcision. Zipper trauma is the most common occurrence. Usually, with local anesthesia, the zipper can be dislodged by simple advancement or at times by cutting the median bar of the zipper, thereby allowing the teeth to separate. Occasionally, circumcision may be warranted acutely.

After the newborn period, the indications for circumcision are relatively few. Circumcision is generally performed under general anesthesia after the newborn period, although the use of local blocks and circumcision

in boys beyond this period has been reported.[16] Depending on the age of the patient and the size of the penis, surgical excision and suturing or newborn clamps may be used. The procedure is usually successful with low complication rates and is performed on an outpatient basis. Recovery is generally prompt, with older patients experiencing more discomfort and having a longer recovery period.

GENITAL HOLDING

Children who hold or clutch their genitalia are often of concern to their parents. This behavior begins shortly after toilet training and may last through the prepubertal years. It is more common in boys than girls. In boys, some degree of genital holding is almost universal. This behavior is thought to have no significant sexual or psychological implications[1] and is thought to be normal and does not warrant any diagnostic studies. Seldom is there any underlying physical cause, and evaluation beyond physical examination and urinalysis (UA) is not warranted. The best advice for parents is to have them redirect the child's attention without placing great emphasis on this behavior. Generally, over time, children learn more acceptable public behavior without the apparent preoccupation for genital holding. Occasionally, very persistent holders may be told that the behavior may make others uncomfortable, and that for this reason, if they must hold themselves, they should do this in private. Parental education and reassurance is the best course of management.

URETHRAL PROLAPSE

The circumferential eversion of urethral mucosa through the urethral meatus may be seen in girls and is termed urethral prolapse. It is associated with vascular congestion and possible strangulation of the prolapsed tissue. It is possible to have a partial or incomplete prolapse, but complete urethral prolapse is more common.[17] The etiology of urethral prolapse is unclear. Suggested causes include poor attachment between the inner longitudinal and outer circular and oblique smooth muscle layers of the urethra associated with antecedent episodes of increased abdominal pressure, mucosal redundancy and vaginal mucosal atrophy, estrogen deficiency leading to lax periurethral fascia, neuromuscular disorders, urethral malposition, increased width of the urethra, poor bladder support, and deficient elastic tissues.[18] Predisposing Valsalva maneuvers, such as chronic coughing, asthma, and constipation, as well as UTI and trauma, have been reported.[19–22] Urethral prolapse is often misdiagnosed as the cause of urogenital bleeding in girls. The correct diagnosis at presentation has been reported in only 21% of cases.[23] It is important to recognize that the prolapse appears as a doughnut-shaped mass protruding at the vulva (Figure 10.9). The mucosa is edematous, friable, bright red, or blue-black. As time goes on, it may become infected, ulcerated, necrotic, or gangrenous.[17] The differential diagnosis of urethral prolapse includes a prolapsing ectopic ureterocele, a prolapsed urethral polyp, an ectopic ureter, a prolapsed bladder, a urethral cyst, hydrometrocolpos, condyloma acuminatum, sarcoma botryoides, and a periurethral abscess. The diagnosis of urethral prolapse is visual and based on the typical circumferential appearance of the lesion around the meatus. None of the other stated conditions have a similar appearance. At times, diagnostic confirmation is made by placing a catheter or an instrument tip demonstrating that the urethra is actually in the center of the edematous tissue. Imaging studies are not necessary, but a voiding cystourethrogram (VCUG) can show a narrow, distal urethra.[24] The age range at diagnosis in pediatric series is from 5 days to 11 years, with a mean of 4.5–6 years.[20,22,23,25,26] Urethral prolapse has been reported in identical twins.[27] There is a significant preponderance of urethral prolapse in patients of African descent, with reports being 90% or greater.[20,23,28] A recent study supports previously reported findings by other authors in terms of demographics and clinical presentation.[29]

FIGURE 10.9 Urethral prolapse: note the doughnut appearance with urethral meatus centrally.

In addition to bleeding, symptoms include dysuria or frequency in 25% of cases.[20,22,23,25] Nine percent of the patients are asymptomatic, with the urethral mucosa showing no tenderness.[17,22] Urogenital bleeding due to urethral prolapse may be mistaken to be from a vaginal source.[20,22,23,25,30]

Treatment options vary for urethral prolapse. Simple treatments should be tried first, including observation alone, topical antibiotic ointment, topical estrogen cream,

and sitz baths. Surgical treatments include primary excision, reduction and catheterization, and suture ligation of the prolapsed tissue over a catheter, and in adult women, cryoablation has been reported.[31] Most published series recommend conservative therapy.[20,23,25,29,30,32,33] Surgical treatment should be reserved for those rare instances of recurrence or persistent, symptomatic prolapse.[18,20,23,25,30]

LABIAL ADHERENCE

Labial adherence, midline fusion of the labia minora, is a common acquired lesion in young girls. Before puberty, the labia minora are covered with a thin hypoestrogenized epithelium.[28,34] An irritating event, such as infection, trauma, or inflammation, causes the area to become denuded and inflamed, and the medial labial surfaces adhere with a fibrinous exudate over their surfaces.[28] Perhaps the most common inciting event is ammoniacal irritation. Adherence generally begins posteriorly and progresses anteriorly, leaving a small opening for the urine just inferior to the glans clitoris (Figure 10.10).[35] Occasionally, the process begins near the clitoris, forming a preputial fusion.[28] Labial adherence is also known as labial adhesions, labial agglutination, gynatresia, vulvar fusion, coalescence of the labia minora, vulvar synechiae, labial fusion, and occlusion of the vaginal vestibule. Differential diagnosis includes scarring of the labia minora, imperforate hymen, vaginal agenesis, clitoral hypertrophy, or disorders of sexual differentiation.[34]

FIGURE 10.10 Labial adhesions characterized by fusion of the labia minora. There is generally a small opening anteriorly.

Labial adherence is fairly common and accounts for a large number of the genital abnormalities seen in girls. The peak incidence is between birth and 2 years old, and again around the age of 6–7 years, although fusion can be seen until puberty.[35,36] Most girls with fused labia are asymptomatic, but some have a deflected urinary stream or vaginal pooling of urine. Dysuria, generally secondary to the underlying inflammatory process, may be a persistent complaint. Patients may present with the diagnosis of UTI;[35,36] however, the suspected infection may simply be a contaminated specimen, as urine pools beneath the fused labia before exiting. True adhesion of the labia can occur in sexually abused girls with an incidence of approximately 3%.[34,37] This scarring is often thick and irregular in texture, and involves deeper layers.[38]

Treatment of adherent labia minora is not routinely required. Parents and referring primary care physicians should be reassured that they will lyse spontaneously given time. If treatment is thought to be necessary, estrogen cream can be applied daily, with success reported to be as high as 90% at 8 weeks.[34] The side effects of the estrogen cream will include vulvar pigmentation in all of the patients and breast tenderness in 6%, which resolves after the estrogen therapy is discontinued.[35] However, the long-term effects of estrogen given to prepubertal girls are unknown, along with potential malignancy risk; therefore, treatment beyond a few weeks is probably unwarranted. In an effort to avoid the side effects associated with application of estrogen cream, some have used 0.05% betamethasone ointment in one to three courses lasting 4–6 weeks each, with success in up to 68% of patients, including some in whom estrogen cream had been unsuccessful.[39] Persisting adherence can be separated in the office using topical anesthetic (EMLA) and gentle, blunt separation.[28,34,35] An oral anxiolytic may be considered in such girls for this procedure. Following separation, daily separation of the labia with application of an ointment should be continued for a time to prevent recurrence.[34,35] Forceful separation without analgesia is not recommended.

VAGINAL CYSTS

Incidental vaginal cysts are uncommon and are often found in the newborn period, possibly as a consequence of stimulation by maternal estrogens. They are usually single and between 1 and 3 cm in diameter. When recognized in newborns, evaluation should include passage of a catheter or instrument into the vaginal introitus to ensure patency. Rarely, ultrasonography (U/S) may be necessary to ensure that the vagina is normal and not obstructed. These cysts almost always rupture spontaneously or resolve over a few weeks and need no further treatment. Introital cysts are of several types, including Gartner's duct cyst, Müllerian duct cyst, and epithelial inclusion cyst.

Gartner's duct is the distal rudimentary portion of the Wolffian (mesonephric) duct in girls. These ducts in girls usually regress and almost completely disappear. If remnants persist, they are usually found along the anterolateral walls of the vagina. Flat, cuboidal cells line the cyst.[40]

Gartner's duct cysts present as a perivaginal mass and usually appear in infants.[41] These cysts can be large enough to protrude from the vaginal introitus or fill the vagina and block the opening.[37,41,42]

Müllerian duct cysts are remnants of nonfused portions of the Müllerian ducts. They are generally asymptomatic and do not usually cause problems until menarche.

Most epithelial inclusion cysts are remnants of the urogenital sinus. Following trauma or surgery, buried vulvar or vaginal epithelium may also cause epithelial inclusion cysts. These are rare in children, although not uncommon in older women.[40] They usually occur posteriorly and in the midline of the vagina.[43] The cysts contain thick caseous material with a squamous epithelium lining their inner surface.[40] Surgical excision is the treatment of choice.[42]

HYDROCOLPOS

Distension of the vagina with fluid or mucous secretions is called hydrocolpos. If the uterus is involved, the term is *hydrometrocolpos*. The vagina can be obstructed from an imperforate hymen, transverse vaginal septum, or atretic vaginal introitus.[44] This produces a bulging, shiny, pearly gray protuberance observed over the vaginal introitus.[41,43]

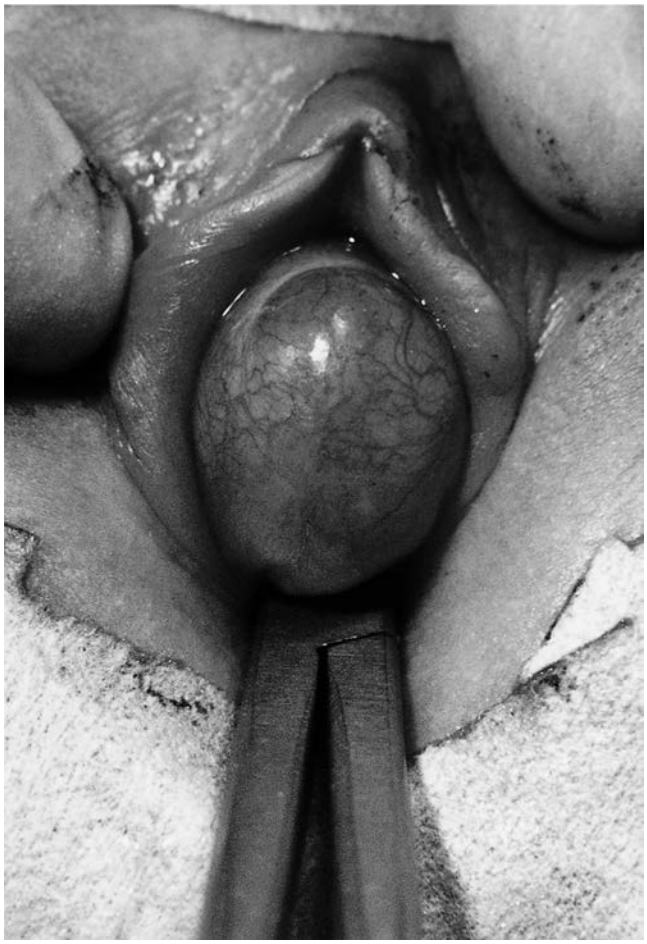

FIGURE 10.11 Hydrocolpos with duplicated vagina. The urethral meatus is seen splayed above the bulging mass while the hemostat is placed in the patent (second) vaginal opening.

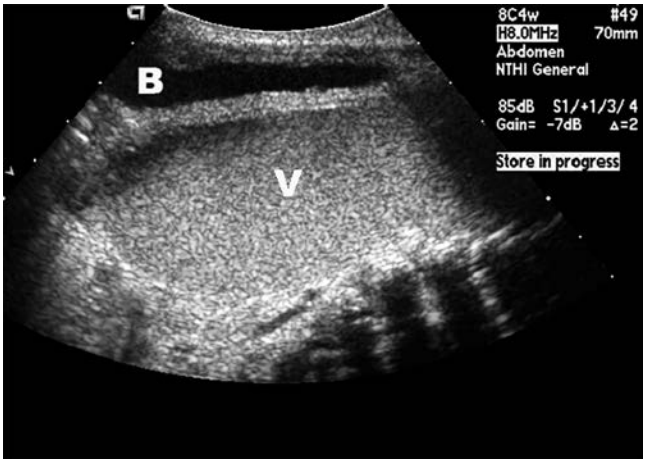

FIGURE 10.12 Ultrasonographic (longitudinal plane) image of hydrocolpos. Nondistended mildly thickened bladder wall (B) present anteriorly. Dilated vagina (V) with hyperechoic cellular and fluid debris present.

The urethral meatus can be noted anterior to the mass (Figure 10.11). Large abdominal masses can be palpable or identified on U/S (Figure 10.12). Occasionally, urinary retention can be due to a mass effect. U/S shows a retrovesical oval cystic mass occasionally causing hydroureteronephrosis.[45] Treatment consists of drainage of the obstructed vagina perineally, but occasionally temporary abdominal vaginostomy may be necessary.

OTHER INTERLABIAL MASSES

Periurethral cysts are known to occur along the distal one-third of the urethrovaginal wall.[40] The urethral meatus can be displaced, causing compression and a deflected urinary stream or dysuria. These cysts usually rupture spontaneously.[44,46]

VAGINITIS

Vulvovaginitis is the most common cause of vaginal bleeding in the pediatric age group.[47] Vulvitis is vulvar irritation secondary to trauma, topical allergens, mechanical irritation, chemical irritation, or poor hygiene.[48] Vaginitis is erythema and inflammation of the vaginal mucosa generally associated with discharge. Vulvovaginitis is very often a self-limiting problem and immediate workup is not necessary. As the symptoms persist or become more annoying, workup should include sampling of the vaginal pool for pH, wet mount, potassium hydroxide swab, and examination for chlamydia and gonorrhea. A UA with culture may be diagnostic. If specific treatment is desired, a definitive diagnosis must be made.[47] Noninfectious causes in infants and children should be investigated, including ruling out the presence of a foreign body. Foreign body vaginitis symptoms are similar to other types of vaginitis. Toilet paper remnants are the most common objects found in the vagina.

NONSPECIFIC VULVOVAGINITIS

Nonspecific vulvovaginitis refers to a nonpurulent, nonodorous discharge with a neutral pH and normal flora on wet mount. It accounts for 25%–75% of all vulvovaginitis seen in premenarchal girls.[46] The etiology includes poor hygiene, urinary soiling, tight clothing, or chemical irritants, such as harsh soaps. When testing is normal, treatment consists of reassurance and encouragement of good hygiene and appropriate clothing.

NEWBORN PHYSIOLOGIC LEUKORRHEA

It is normal for newborn girls under maternal estrogen stimulation to have a vaginal discharge. It is usually clear with white-gray mucus not associated with odor or irritation. Wet mount shows numerous epithelial cells without pathogenic bacteria or leukocytes. The discharge diminishes once maternal estrogen stimulation subsides. The tendency toward treatment with vaginal creams and antibiotics should be discouraged.

SEXUALLY TRANSMITTED DISEASES

A common sexually transmitted disease is chlamydia, caused by *Chlamydia trachomatis*, which is an obligate intracellular gram-negative organism capable of infecting the atrophic cuboidal epithelium of the prepubertal nonestrogenized vagina.[48] Young children may acquire chlamydia by passing through an infected birth canal or by sexual abuse. In newborns, chlamydia may infect the conjunctiva, pharynx, vagina, or anus. It is estimated that 50%–75% of newborns become infected if their mothers were infected with chlamydia.[49]

Gonorrhea is the most common sexually transmitted disease in abused children and is not likely in children who are not sexually abused.[48,50] It is important to recognize gonorrhea to prevent sequelae and to recognize the child who is sexually abused. Infants can be contaminated through vaginal secretions in the birth canal colonizing the oropharynx, vagina, and rectum. The infection may remain asymptomatic. However, a white, yellow, or greenish, thick vaginal discharge with odor may be present. Labial erythema, urethral irritation, proctitis, or dysuria may be present.

YEAST INFECTIONS

Other than the cutaneous variety associated with diaper rash, yeast infections are more common in adult females than in prepubertal girls. The alkaline vaginal pH of childhood is hostile to yeast.[48] Most yeast vaginitis is caused by *Candida albicans*. Most often, yeast infections are secondary to predisposing host factors, such as broad-spectrum antibiotic use or depressed cellular immunity.

BACTERIAL VAGINOSIS

Less commonly, vaginal infections can be due to bacteria and are often listed as nonspecific or *Gardnerella* vaginitis. This is now recognized to be caused by a mixed flora, including anaerobic bacteria.

PEDIATRIC HEMATURIA

The presence of blood in the urine is a common clinical entity resulting in referral to pediatric urologists. It is a manifestation of abnormalities localized to the urinary tract from the kidneys to the urethra. Hematuria may be visible grossly or seen only on microscopic examination. Urine dipstick measures the presence of hemoglobin in urine and can be falsely positive for hematuria when hemoglobinuria and myoglobinuria are present. Verification of a positive urine dipstick for blood using microscopy can be performed to identify red blood cells (RBCs) within the specimen. To be considered significant for hematuria, UA requires five RBCs per high-power field. RBC casts, dysmorphic or fragmented RBCs, and RBC blebs on UA signify a glomerular source for hematuria. Gross hematuria accounted for an estimated 1–2 patient visits per 1000 in pediatric emergency clinics.[51,52] The incidence of microscopic hematuria in asymptomatic children ranges from 14 to 41 per 1000 individuals when a minimum of four urine specimens was collected.[53,54]

The evaluation of a child with hematuria should be guided in a systematic fashion as determined by history, physical exam, and laboratory tests. Questions regarding the timing of hematuria relative to gastrointestinal, cutaneous, and respiratory infections are important. The presence of UTI symptoms, including dysuria, flank pain, fevers, chills, frequency, and urgency, and a history of recent trauma or prolonged or vigorous exercise add direction to the initial assessment. The character of blood in urine (terminal vs. throughout voiding), passage of clots, and signs of stone passage, including flank pain, nausea, vomiting, and radiating pain, associated with hematuria should be recorded. Documentation of any family history of renal failure, deafness, sickle cell traits or disease, and recurrent hematuria should clue the clinician to a hereditary source of hematuria. Medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and certain chemotherapeutic drugs, can be causative in the development of hematuria.

Physical exam should identify the presence or absence of flank or abdominal tenderness, extremity edema, pharyngitis, cutaneous rashes, deafness, fever, and hypertension. Urinalyses demonstrating proteinuria and/or abnormalities of RBC morphology are present in diseases involving the glomerulus or its basement membrane. Nitrites, leukocyte esterase, white blood cells (WBCs), and bacteria should prompt urine culture to tailor antibiotic treatment. Further laboratory and radiographic testing should be based on clinical suspicion.

Asymptomatic microscopic hematuria is often identified when routine screening urine dipsticks are obtained in children. The absence of an inciting event (i.e., trauma),

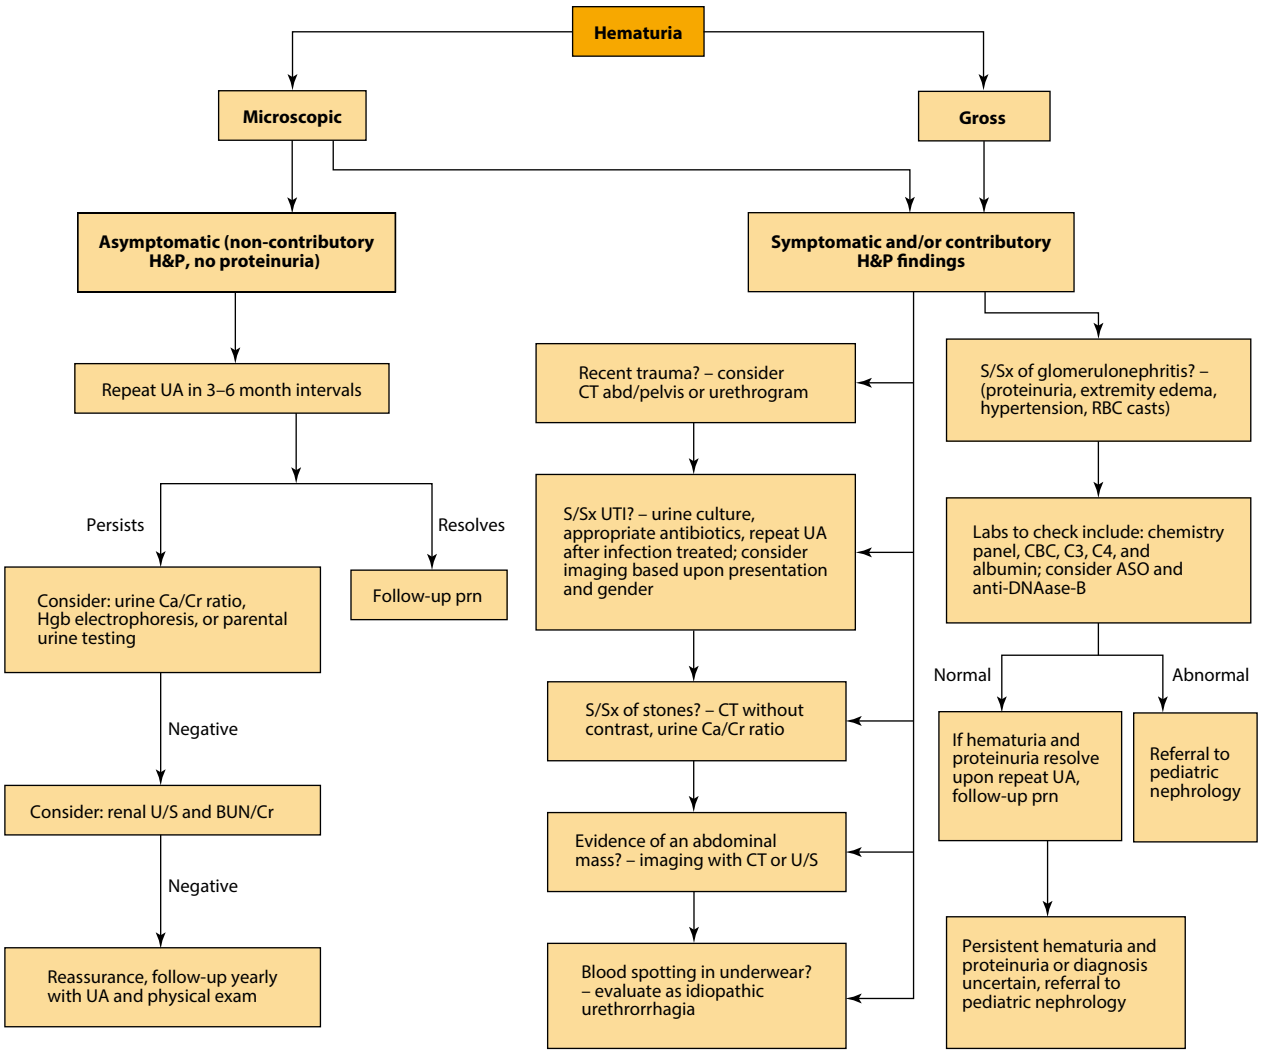

FIGURE 10.13 Diagnostics algorithm for pediatric hematuria. For abbreviations see text. In addition: BUN, blood urea nitrogen; S/Sx, signs and symptoms; prn, as required; H&P, history and physical examination; Hgb, hemoglobin.

proteinuria, infection, hypertension, lower extremity edema, and renal insufficiency is reassuring, and most of these patients can be observed with follow-up UA in 3- to 6-month intervals until they normalize. When attributable to vigorous exercise or medications (i.e., NSAIDs), repeat UA can be performed every 1–2 weeks after discontinuation of the offending source, to confirm resolution of the hematuria. Diagnostic tests, such as radiographic examinations (U/S or VCUG), or invasive procedures, including renal biopsy or cystoscopy, are not warranted in these patients.[55] If asymptomatic gross hematuria or persistent microscopic hematuria occurs, diagnostics testing can be tailored based on history and physical examination.

When persistent microscopic hematuria develops without a contributory history or physical examination, obtain the calcium/creatinine (Ca/Cr) ratio, parental UA, and hemoglobin electrophoresis (if the patient is of African American descent), to assess for hypercalciuria, benign familial hematuria, and sickle cell disease or traits, respectively. The spot Ca/Cr ratio is considered abnormal when greater than 0.21 in children older than 6 years of age.[56] Alternatively, a 24-hour urine collection demonstrating a urine calcium level greater than 4 mg/kg/day is diagnostic for hypercalciuria.[57] In a small retrospective study of children referred for microscopic hematuria,[55] evaluation of serum electrolytes, creatinine, cystoscopy, VCUGs, and U/S of the kidneys and bladder failed to show abnormalities. However, serum creatinine and renal U/S are often utilized to assist in the initial evaluation despite their apparent low yield. When normal, parents can be reassured that their child's prognosis is excellent. Nonetheless, these patients should be followed yearly to assess for the development of proteinuria, hypertension, or new symptoms, or the resolution of hematuria that would alter current management.

When microscopic hematuria is associated with symptoms, patient evaluation should be tailored based on clinical presentation. The concomitant presence of proteinuria, hypertension, and peripheral edema should prompt an assessment to distinguish between glomerular etiologies of hematuria. Laboratory tests, including a chemistry panel, complete blood cell count (CBC), C3, C4, albumin, anti-streptolysin-O, and anti-DNAase-B antibodies, will

facilitate discriminating between the different immune and basement membrane abnormalities. Prompt referral to a pediatric nephrologist should occur in the presence of an acutely ill child, rapidly progressing or chronic glomerulonephritis, patients exhibiting symptoms of nephritic syndrome, uncertainty of a correct diagnosis, or the need of assistance in management and therapy.[58] However, when microscopic hematuria is associated with a small amount of proteinuria, a conservative course with close follow-up can be instituted with further investigation utilizing the above algorithm if evidence of persistence or clinical progression occurs.

If a history of recent trauma is present, computed tomograms (CTs) and retrograde urethrograms are warranted based on the clinical scenario and judgment. When signs or symptoms worrisome for a UTI are present, protocols should include obtaining urine cultures, instituting antibiotic therapy based on culture sensitivities, and repeating a formal UA and culture after the infection has been treated to assess for resolution of the hematuria. Noncontrast CT and urine calcium analysis are helpful if urolithiasis is suspected, and abdominal imaging (U/S or CT) if an abdominal mass is palpated.

The presence of gross hematuria can be differentiated based on its appearance. Tea- or cola-colored urine suggests a glomerular source. Bright red urine with normal morphology on microscopic examination suggests a urothelial etiology for the hematuria.[59] The absence of RBCs on microscopic examination in light of a positive dipstick may be indicative of hemoglobinuria or myoglobinuria. Subsequent workup for gross hematuria is driven primarily by clinical presentation. Signs and symptoms suggestive of stones, infection, recent trauma, or glomerulonephropathies can follow protocols similar to those described for symptomatic microscopic hematuria.

Idiopathic urethrorrhagia is seen in prepubertal boys who present with blood spotting in the underwear between voiding. In a review at our institution, dysuria was reported in ~30% of patients and the mean age at presentation was 10.1 years old.[60] Laboratory and radiographic studies—intravenous pyelography (IVP), U/S, and VCUG—are routinely normal, although RBCs can be seen in up to 57% of patients.[60,61] Symptoms can persist, ranging from a few weeks to 3–4 years. Etiology is unknown, although anterior and posterior urethritis has been documented.[60,62] Cystoscopy is generally considered unnecessary unless symptoms persist greater than 24 months, as urethral stricture may be identified. This process is self-limited and resolves by puberty without treatment.

For a review of the diagnostic algorithms presented for pediatric hematuria, refer to Figure 10.13.

CHAPTER 11

Principles of Minimally Invasive Surgery

Walid A. Farhat and Pasquale Casale

INTRODUCTION

Laparoscopy is now a popular surgical approach in pediatric urology, reducing the invasiveness of treatment and shortening the period of convalescence. At present time, with the development of new instruments better designed for pediatrics, laparoscopy in all ages may be a safe and effective way to treat a variety of urologic disorders. Since pediatric urologists lack the luxury of being exposed to common and frequent surgical procedures aside from pyeloplasty and nephrectomy, it is natural that the learning curve is steep. Hence, in order to master this surgical modality and technique, the novice must acquire a set of basic knowledge in pediatric physiology pertaining to laparoscopic surgery, and be adept to current and fast-evolving technology, while being exposed to a large number of cases where the laparoscopic approach may be incorporated.

Prior to any surgical procedure, a brief description of the surgical approach and patient positioning, in addition to a list of the needed instruments during the surgery, should be gone over with the operative team, nurses, and anesthesiologists. In addition, the surgeon should become familiar with the available laparoscopic instruments and comfortable with troubleshooting the tower, insufflation, and other common issues that may occur during laparoscopic procedures.

PATIENT SELECTION AND PREOPERATIVE EVALUATION

The majority of children are good candidates for minimally invasive intervention, either laparoscopy or robotic procedures. There are, however, relative contraindications, such as poor cardiopulmonary reserve and impaired CO_2 exchange, as well as absolute contraindications, such as intra-abdominal infection, that would prohibit insufflation of the abdomen.

Other relative contraindications that are dependent on the dexterity of the surgeon are bowel adhesions and previous abdominal surgery, in addition to peritoneal dialysis. A history of previous abdominal surgery can sometimes be circumvented with adequate visualization and meticulous dissection. Finally, a relative contraindication is bleeding diathesis.

Preoperative testing in infants should include a prothrombin time (PT), partial thromboplastin time (PTT), hemoglobin, hematocrit, and creatinine, with urine culture, especially if there is a bladder or urinary system intervention to be performed. Similar recommendations, such as hematology or cardiology or pulmonary consults, are only recommended if the patient has a history of bleeding tendency or cardiac or pulmonary disease. Traditionally, most of the children that undergo routine laparoscopy procedures, such as nephrectomy or pyeloplasty, would benefit from a baseline hemoglobin or hematocrit, although many would consider this unnecessary in the healthy child.

PEDIATRIC PHYSIOLOGIC CHANGES

Anesthesia

Induction and maintenance of anesthesia may be achieved with either inhalational or intravenous agents or a combination of both. Nitrous gas increases bowel distention, potentially bringing the peritoneum closer to the area of dissection for retroperitoneal procedures and furthermore decreasing the working space in transperitoneal procedures.

Like any surgical procedures, intraoperative monitoring should include a routine electrocardiogram (ECG), noninvasive blood pressure, SpO_2, temperature, and inspired oxygen concentration. Although end-tidal CO_2 may not accurately reflect arterial CO_2 tension, its use is helpful in planning appropriate ventilation strategies in case pulmonary decompensation occurs after CO_2 insufflation. In infants and children with respiratory illness, capillary or arterial blood gas analysis might be needed to accurately monitor CO_2 tension.[1] Maintenance of intravenous fluid is usually sufficient unless there is unanticipated bleeding, keeping in mind that urine output is usually low during insufflation and does not reflect dehydration.[2]

Anesthesia and Positioning

Although positioning is intended to facilitate surgery and improve the ergonomics of the surgical team, it is evident that pediatric patients not only have a small intracorporeal space, but also may have a limited extracorporeal space. This restrictive landscape makes it necessary for the surgeon and anesthesiologist to share the space in case an emergency situation erupts. For instance, when patients are placed in flank positions, insertion of the intravenous line in the arm on the side of the surgery allows for easy access.

Furthermore, patient positioning during laparoscopic surgery may potentiate the impact of gas insufflation. For instance, the Trendelenburg position during laparoscopy will increase the heart rate and vascular resistance while decreasing mean arterial pressure and cardiac output, whereas the opposite effect is seen in the reverse Trendelenburg position. Furthermore, flank positioning, especially with the kidney rest up and the patient flexed, will accentuate impaired venous return and increase cardiac strain. In fact, the left lateral decubitus position produces more significant hemodynamic and respiratory changes than the right flank position.[3]

CO_2 and Pressure Effects

As gas is placed in a closed space, it moves depending on the partial pressure gradients. Once the pressure rises, a plethora of cardiovascular, pulmonary, and renal effects may be seen (Video 11.1a,b). The heart rate and mean arterial pressure increase while the venous return and cardiac output decrease. These parameters are seen even when pressure is set at a standard working level of 10–15 mmHg. Above this level, more profound hemodynamic alterations are anticipated to occur, with a further decrease in cardiac output. Furthermore, limitation of diaphragmatic mobility may cause respiratory restriction manifested by increased airway pressure, requiring an increase in the peak end-inspiratory pressure to maintain a set tidal volume. Finally, renal effects occur secondary to gas insufflation, manifested by decreased glomerular filtration rate (GFR) and urine output. Animal studies have shown that gas insufflation causes renal vein compression, including decreased renal blood flow, decreased urine output, and diminished creatinine clearance. Although these effects do not cause renal damage in humans,[2] it is crucial and important information that the operating surgeons know about.

Traditionally, in the pediatric population the insufflation rate should be based on the age or weight of the patient. In patients that are younger than 1 year of age, we usually use a 0.3 L/min flow; while in patients between 1 and 5 years of age, we use 0.5 L/min. In patients between the age of 5 and 10 years, we use 1 L/min flow, and for patients older than 10 years, we usually use 2 L/min. With the onset of insufflation, surgeons and assistants need to be competent to address any of the possible complications that may occur, such as CO_2 embolism or pneumothorax. CO_2 embolism is manifested by right heart failure, whereas pneumothorax is manifested by an acute drop in oxygen saturation.

Absorption Effects

Although the absorption of the insufflated CO_2 into the blood is limited, its diffusion is determined by many variables; most important are the pressure differential and the cross-sectional area of the absorbing surface. Both the peritoneal and retroperitoneal spaces are closed yet expansible. The physiologic consequences of CO_2 insufflation may be related to the compressive effects of the gas or the metabolic consequences of the gas absorption. With insufflation, the gas will attempt to reach equilibrium with the surrounding environment; such equilibrium is controlled with the use of insufflators that not only control the flow of gas but also monitor the feedback pressure generated from the insufflation.

The effects of gas absorption are either pulmonary or hemodynamic. The pulmonary effects are increased CO_2 retention and increased end-tidal CO_2, exacerbated by decreased functional residual capacity and decreased diaphragmatic excursion. The hemodynamic effects of hypercarbia are increased heart rate, vasodilation, and increased cardiac contractility. Although in healthy children there is little, if any, added cardiorespiratory risk from laparoscopic procedures, children with cardiopulmonary compromise require close and careful monitoring.

INSTRUMENTATION

Rapid progress in video technology and the miniaturization of instruments to <3 mm in diameter have made the performance of a variety of pediatric laparoscopic procedures possible. Instruments of this size and larger come in nearly every variety (scissors, needle holders, dissectors, graspers, clamps, suction devices, energy delivery devices, etc.) and facilitate the performance of the most complex cases. Nevertheless, the surgical procedure, in combination with the size of the patient, will determine the surgeon's selection of instruments and telescope size. Laparoscopic trocars are available in 3, 5, and 10 mm sizes, with varying degrees for optimal visualization. For most ablative or reconstructive urologic procedures, 3 or 5 mm trocars are sufficient. However, sometimes 10–12 mm trocars may be necessary if a stapling device needs to be utilized, or when specimen extraction is anticipated.

ACCESS

Traditional Laparoscopy

There are two techniques to gain access into the peritoneum: blind access and access through visualization, often referred to as closed versus open access. The blind closed approach is facilitated through the use of the Veress insufflation needle. A stab wound is made, either in the middle of the umbilicus or just below typically, with either a #15 or a #11 blade. The Veress needle is inserted through the 1 mm opening and passed through all layers of tissue, and verification of placement is confirmed by opening the stopcock and infusing a small amount of saline. For transperitoneal procedures, it may be more accurate to attach the insufflation needle to the insufflator and monitor pressures. Low pressures (<10 mmHg) are a reliable indication of being intraperitoneal. The second technique is the open (Hasson) approach, and this approach may be facilitated through the use of direct and telescopic visualization of all tissue during insertion of the trocar with a blunt obturator. This technique has been generally preferred in children and is especially ideal in obese patients. Another currently preferred technique by many surgeons because it is fast, safe, and accurate is the Bailez incision at the umbilicus

combined with a radially dilating trocar.[4] Placement of accessory ports should be carried out using direct vision from within. The location of the accessory trocars depends on the operation to be performed, and specifics of all trocar placements are described below in the transperitoneal and retroperitoneal laparoscopy subsections of this chapter. All proposed trocar sites are injected with 0.5% bupivacaine, with 1:100,000 epinephrine after insufflation and prior to accessory trocar placement. The purpose of this step is to decrease the postoperative pain and further provide an accurate location of the trocar position, hence avoiding finger pressure in children with a small peritoneal cavity and obscuring the accurate trocar location.

Trocar Fixation

Once the primary trocar is introduced and prior to CO_2 insufflation, a 2-0 Vicryl (UR-6 needle) suture may be placed around the trocar and in the fascia as a purse-string suture (Video 11.2). After the depth of the trocar is well delineated, this suture is tied to the side of the port and serves several purposes: it prevents the trocar from moving in or out during instrument manipulation, it decreases the possibility of subcutaneous emphysema or leakage of CO_2 from around the trocar site, and it can be used to lift the abdominal wall to enlarge the retroperitoneal space.

For the accessory trocars, a short (~1 cm) section of rubber, plastic tubing, or cone can be placed around the trocar shaft, about one-third of the way from the tip to the hub of the trocar. This prevents the trocar from being pushed into the surgical cavity as instruments are advanced. This surgical step is rarely needed, especially if the accessory trocars are inserted through a small stab incision—hence the tight entry site.

Insufflation

Newer insufflators can deliver a great volume of gas rapidly; this may be dangerous in an infant weighing less than 2 kg. In addition to pressure fluctuation, CO_2 insufflation with unwarmed high-flow gas may cool a tiny infant quickly. Whereas the rule is to insufflate with just enough pressure to have unobstructed visualization, pressures of 15 mmHg appear to be well tolerated in any size patient, with the only issue being ventilator compromise in infants with marginal lung function. For all laparoscopic procedures, CO_2 insufflation should be started at a pressure of 12–15 mmHg for children of >2 years old and 8–10 mmHg for children of <2 years old.

Robotics

Today's surgical robots, or what the true enthusiasts call "surgical actuators," allow freedom in the operating room that we only imagined not too long ago. Over the past decade, there have been a series of surgical manipulators, which receive digital instructions from an interfaced computer. Unlike industrial robots, they are not autonomous. Their birth was a reflection of the growth in minimally invasive surgery (MIS), mainly laparoscopy. Laparoscopy, although excellent for extirpative surgery, is a challenging medium for reconstructive surgery in all but the most experienced hands. Minimally invasive laparoscopic surgery has two severe limitations for those who cannot afford to spend the time in specialized training for MIS: (1) only four degrees of freedom, which makes intracorporeal suturing and tying a complicated task, and (2) a lack of three-dimensional visualization. The current industry-supported robotic platform, the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, California), provides the advantages of delicate manipulation for reconstructive surgery combined with three-dimensional visualization (if the largest lens is used). This current robotic platform entails a surgeon seated at an ergonomically designed video console with an "immersive" three-dimensional display. The surgeon initiates the digital instructions by controlling finger grips giving seven degrees of freedom by adding the pitch, the yaw, and a pincer movement to those already existing in MIS. The manipulators inside the patient's body duplicate the surgeon's hand movements at the console, and software carries the capability of filtering out hand tremors.

Robotics can be helpful for manipulation in hard-to-reach places. In urology, radical prostatectomy is performed in a challenging environment: under the pubis in the confined space of the pelvis with limited visualization and movement. The most difficult surgery in regards to open access in adults always seems to be deep in the pelvis. So it is not surprising that robot-assisted prostatectomy is continuing to grow in the United States. The surgeon is not optimized for tight spaces, but the robot is.

Robotic surgery will allow surgeons to perform more complex minimally invasive procedures that may be too tedious and time-consuming with standard laparoscopy. Intracorporeal suturing is a rate-limiting step in pure laparoscopy, and mastery of this technique is time demanding. Robotics allows this step to be facilitated. The robotic software can scale down a surgeon's hand movements into "micromotions," virtually eliminating tremor and allowing the surgeon to be even more precise and accurate than laparoscopic and possibly even open surgery.

The lack of tactile feedback has skeptics concerned. If one takes a step back, one would realize that when we manipulate tissue and the small sutures during pediatric surgery, there is less reliance on tactile feedback. It is mostly done by visual cues. Nonetheless, tactile feedback is currently under investigation, and its addition to the current robotic platform should enhance the performance.

Despite its early success, robotic surgery still poses many challenges in pediatric patients. As in laparoscopic surgery, the small working distance on the abdominal wall in a child can significantly limit the mobility of the robotic instruments. In such a small operative field, a difference of a few millimeters can greatly affect the safety of the operation. The location and placement of the robotic trocars is critical in children and typically requires slight variations compared with placement in adults. Because of the diminished thickness of the abdominal wall, mostly in the infant population, keeping the trocars in place with desufflation during instrument exchange remains a challenge. One technique that might be useful is anchoring the abdominal wall to the trocar with a heavy suture in order to keep the abdominal wall in place if rapid desufflation should occur. The trocars cannot be as deep in the pediatric abdomen as they would be placed in the adults.

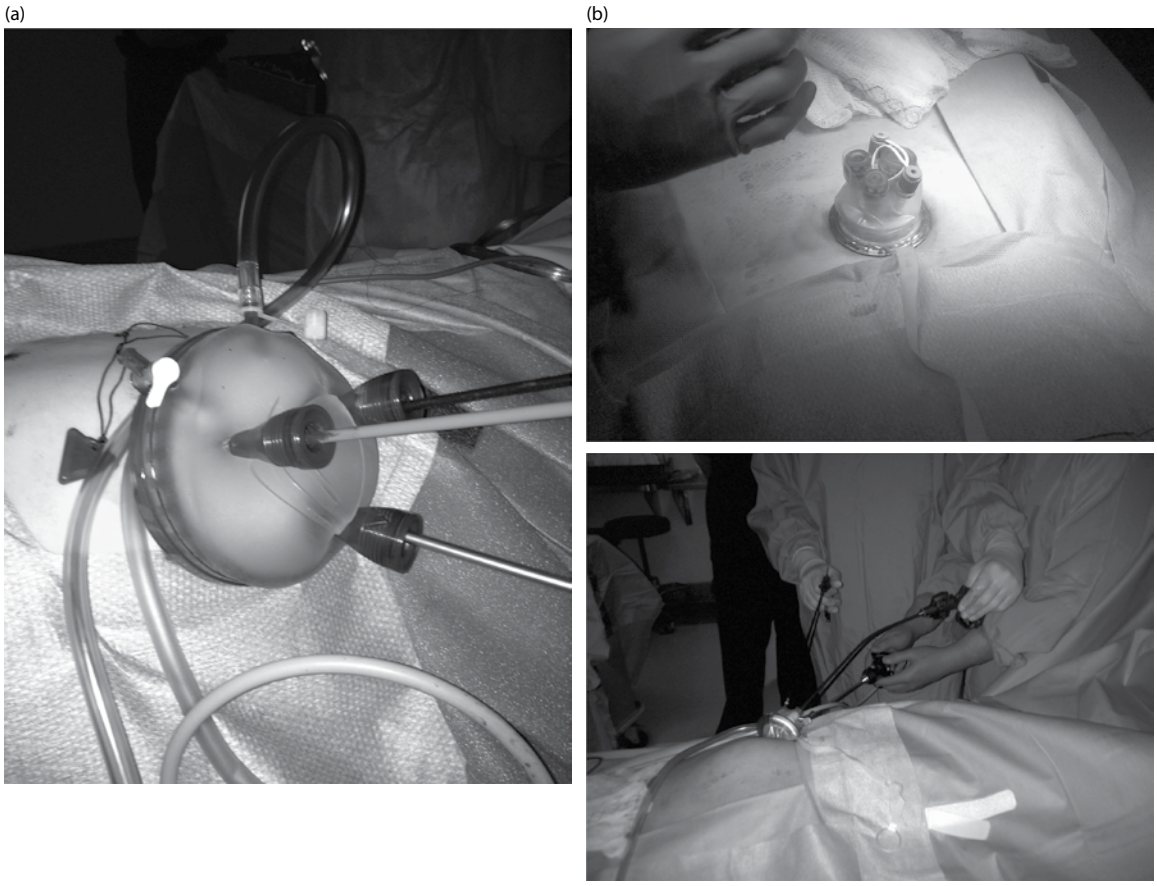

FIGURE 11.1 (a) GelPOINT apparatus in situ. The benefits of this instrument are the triangulation and the ease of use of traditional instruments. (b) Triport (Olympus) is one of the available single-port accesses to perform LESS. Due to the proximity of the ports, specific instruments are usually recommended to be used with this port.

The current surgical robotic platform offers both 12 and 8.5 mm and 0° and 30° telescopes that offer three-dimensional imaging. There is a 5 mm endoscope available, but it is monocular and cannot provide the three-dimensional image of the larger scope. The working ports come in 8 and 5 mm trocars. The robotic device is docked from the ipsilateral side in the upper urinary tract surgery or the foot of the bed in the lower urinary tract surgery and orchiopexy, and the robotic arms are engaged. The robot has instruments that are available in both 8 and 5 mm sizes that complement traditional laparoscopic instrumentation, with a slight paucity of instruments in the 5 mm category. A fourth arm is available for grasping and retraction, but in the small pediatric patient, this arm has limited use.

Laparoendoscopic Single-Site Surgery

Although laparoendoscopic single-site surgery (LESS) is feasible in children, its role, cost-effectiveness, and outcome in comparison with traditional laparoscopy have not been established. Initially, LESS procedures primarily used existing laparoscopic and endoscopic equipment to perform simple procedures, such orchiopexies or varicocelectomies.[5] But the development of improved laparoscopic cameras, as well as articulating instruments, helped to overcome coaxial limitations and "sword fighting" of instruments. The EndoEye™ (Olympus), for example, is a 5 mm scope that has a digital chip at the deflectable tip that provides a wider field of view. This advanced technology, coupled with articulating instruments, allowed the use of this approach in a variety of procedures, including nephrectomy and pyeloplasty.[6]

Currently, LESS is performed using multiport divides, which is a multiple-instrument access port. This port usually will accommodate a scope and two or three additional instruments. There are a variety of access devices available on the market and produced by several manufacturers, for a variety of procedures (Figure 11.1). In children, the traditional location of the single incision used for procedures is the umbilicus (Video 11.3a,b). The umbilical incisions for LESS are usually scarless and may be particularly well suited to procedures such as nephrectomy or pyeloplasty (Figure 11.2).[7]

OPERATIVE APPROACHES

Retroperitoneal Approach

Indications for Retroperitoneal or Transperitoneal Laparoscopy

- Total nephrectomy.
- Partial nephrectomy for duplicated renal system.

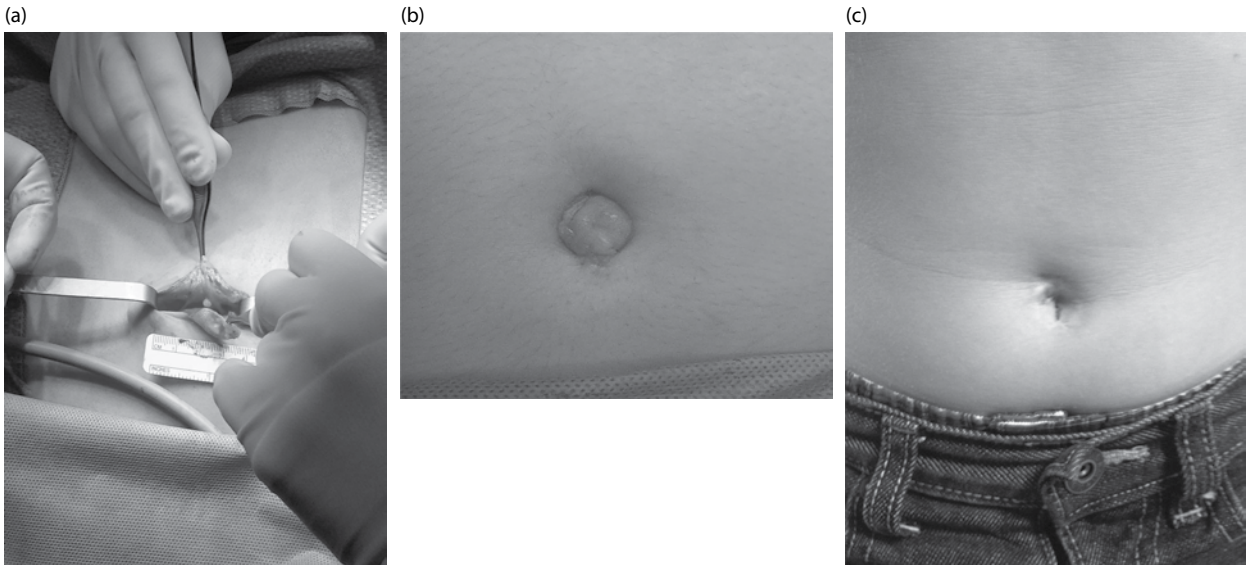

FIGURE 11.2 An umbilical incision is the current approach for LESS in children. A skin incision (a) is performed on the protruding umbilicus, and then with adequate retraction, a generous fascial incision to accommodate the single port is made. Immediate postoperative view (b) of the umbilical incision and a few months later on follow-up (c).

- Distal ureterectomy for duplication anomaly.
- Pyeloplasty.
- Pyelolithotomy and ureterolithotomy. Extracorporeal lithotripsy and endourologic procedures have almost eliminated the need for open surgery to remove urinary stones. On the other hand, in patients who have unusual anatomy, such as ectopic kidneys, a laparoscopic approach may be used either to perform pyelolithotomy or to help in getting direct percutaneous access to the kidney.
- Adrenalectomy for cortical adenoma associated with congenital adrenal hyperplasia.

Contraindications to Laparoscopy

Contraindications to laparoscopy in infants, children, and adolescents are the same as for any other surgical procedure, except for evidence of limited lung reserve function, which may be considered a relative contraindication. If the patient is septic, in shock, or exhibits a coagulopathy, these should be corrected before surgery is contemplated. If surgery is deemed essential under these circumstances, then it probably should be performed open.

Strong contraindications:

- Cardiopulmonary morbidity.
- Uncorrected coagulopathy.
- Sepsis.
- Malignant tumors. Although laparoscopy may play a role in the staging of malignant pediatric abdominal tumors, such as Wilms' tumor or neuroblastoma, its role in the management of these tumors has yet to be defined. Morcellation of specimens for extraction has raised concerns about accurate pathologic staging; hence, large-sized tumors mandate an incision to retrieve them. In addition, the fragile consistency of the tumor makes it more prone to rupture, and hence may obviate the use of this technique.

Retroperitoneal Laparoscopic Approach

Relative contraindications:

- Prior retroperitoneal scar (kidney surgery, kidney biopsy, or pyeloplasty)
- Previous infectious or inflammatory retroperitoneal process (xanthogranulomatous pyelonephritis), except for experienced surgeons in this approach

Advantages:

- The technique mimics the open urologic surgical procedure through the retroperitoneal approach.
- This direct approach to the organs of the genitourinary tract requires less dissection to the colon or the spleen to expose the kidneys and adrenals.
- Previous transperitoneal surgery does not preclude retroperitoneoscopy.
- Trocar sites have less postoperative hernias than an open incision.
- It facilitates the view of the posterior surface of the kidney, and hence rapid access to the renal hilum.

Disadvantages:

- Manipulation of instruments may be initially difficult due to a restricted working space; e.g., in reconstructive surgery such as pyeloplasty, suturing and knot tying may be difficult, and in ablative surgery, the degree of technical difficulty increases in the presence of large-sized specimens.
- Achieving anatomic orientation may initially be a challenge for the inexperienced laparoscopist.

Patient Preparation and Positioning

Bowel preparation for retroperitoneoscopic renal surgery in children is not recommended. Although the

retroperitoneal approach may be accomplished with the patient prone,[8] we prefer the flank position, as it increases the anteroposterior dimensions of the retroperitoneal space and is a suitable position in cases where we need to convert to transperitoneal or open approaches. The patient is positioned in the full 90° flank position as close to the posterior edge of the table as possible. To further increase the retroperitoneal space, the table is flexed and the kidney rest elevated. Pressure points are padded and an axillary roll is placed to prevent postoperative complications, such as brachial plexus palsy. The patient should be taped to the table using 3-inch adhesive tape placed across the shoulder and the hips so that the patient will remain secured while the table is moved during the surgery.

We prefer to have the surgeon and assistant standing on the same side of the table, and we use only one monitor. We believe that having both the surgeon and the assistant in the same line of vision facilitates eye–hand coordination, particularly that of the assistant surgeon.

Anatomic Considerations for Retroperitoneal Laparoscopy

An understanding of the retroperitoneal surgical anatomy is mandatory before embarking on retroperitoneal surgery. The boundaries of the retroperitoneal space are

- Posteriorly and laterally—the paraspinous, psoas, and quandratus lumborum muscles, which are anatomically fixed structures
- Anteriorly—the mobile posterior parietal peritoneum and its contents
- Superiorly—the diaphragm
- Inferiorly—contiguous with the extraperitoneal portions of the pelvis

The retroperitoneum contains the great vessels, kidneys, adrenals, and ureters, in addition to the perirenal adipose and areolar tissues. Since there is no preformed space, pneumoretroperitoneum is only accomplished after breaking up the adipose areolar tissue in the retroperitoneum.

Laparoscopic Technique

Access to the retroperitoneum is preferably achieved by the open (Hasson) technique, which provides visual guidance (Video 11.4a,b). As children have a small retroperitoneal space, and close proximity between the abdominal wall and the major vessels, the closed technique is not recommended. In addition, since there is no actual preexisting retroperitoneal space, the placement of a Veress needle is not precise and may cause injury to either the great vessels or pneumoperitoneum.

In the midaxillary line, a 1 cm long incision is made 1–2 cm below the tip of the 12th rib. The muscles are split in the direction of their fibers, and then the lumbodorsal fascia is incised to enter the retroperitoneum. The method of the development of the retroperitoneal space using a blunt instrument or the balloon dissector is up to the surgeon. Although commercial balloon dissectors are readily available, an inexpensive balloon can be made using the finger of a surgeon's glove tied around a catheter. The balloon is inserted anterior to the psoas muscle and outside Gerota's fascia, and approximately 400–500 mL of air is used to inflate the balloon, creating the space. Instead of using a balloon, we introduce a wet gauze close to the posterior muscular wall to create the retroperitoneal space.

Insertion of the primary trocar in the correct space is of paramount importance because inserting the trocar too far medially may result in peritoneal entry or colon injury, whereas entering posteriorly in the quadratus or psoas muscle may cause bleeding. If Gerota's fascia is easily visible, it is incised and opened for direct CO_2 insufflation, although this technique may be associated with inadvertent peritoneotomy. For this reason, it is preferable to create the retroperitoneal space outside Gerota's fascia, dissect the peritoneum medially, insert the posterior secondary 5 mm trocar, open Gerota's fascia under vision, and proceed with the creation of the retroperitoneal space by medially dissecting the peritoneal reflection for the third trocar insertion.

We exclusively create the retroperitoneal space using blunt dissection, using a wet sponge that is inserted in the retroperitoneal space and advanced inferiorly toward the pelvis and superiorly. In very small children, the sponge may need to be cut in half. Through the incision and with the psoas muscle as a reference point, a 10 mm trocar with the laparoscope (0°) is inserted to confirm correct placement. Initially, the posterior inferior aspect of Gerota's fascia and the lower pole are visualized. Identification of the psoas muscle posteriorly is crucial; on the other hand, anteriorly, the edge of the peritoneum is identified and swept medially to expose the underside of the tranversalis fascia. To avoid tearing the peritoneum, it is dissected medially by manipulating the laparoscope in a lateral to medial fashion close to the abdominal wall to expose the internal surface of the transversalis muscle. Having created the working space, two 5 mm secondary trocars are inserted. The posterior secondary port is inserted approximately midway between the 12th rib and the iliac bone, and lateral to the border of the paraspinous muscles. Using a grasper through this trocar, the peritoneum is further mobilized to create the pelvic extraperitoneal space. The anterior secondary trocar is inserted at the anterior axillary line 2 cm superior to the iliac crest. Although the space may be limiting, the two secondary ports should be inserted as far apart as possible to improve ergonomics.

In order to place the secondary trocars under vision, a 30° laparoscope may be used. However, we use the 0° telescope, and we insert the trocars in the following fashion for both the retroperitoneal and the transperitoneal approach. A small skin stab is made using a #11 blade, after anesthetic is injected. Through the stab incision, a straight clamp is advanced and the fascia is stretched; then using sharp-tipped obturators, the trocars are advanced through the muscles and fascia. Once in the retroperitoneal space, a blunt-tipped obturator is exchanged for a sharp one and the trocars are advanced into the retroperitoneum. This safety tip prevents injury to the peritoneum or the major vessels. In addition, while inserting the trocar, it should be directed toward the area of dissection because if the trocar is advanced away from the site of dissection, this might result in constant tension on the skin during surgery or a greater chance of gas leakage at the trocar site.

Although the sites of the telescope and other trocars are the same for all retroperitoneal renal and adrenal laparoscopic procedures, the sequence of operative strategy and the need for accessory trocars depend on the surgical procedure. In the event that more than three ports are required, laparoscopic guidance and bimanual palpation are recommended for accurate placement. For instance, during retroperitoneoscopic pyeloplasty, an additional port may be required to maintain traction on the ureteropelvic junction for better exposure; in this case, a fourth trocar (3 or 5 mm) is placed along the anterior axillary line at the tip of the 11th rib. In order to avoid inadvertent peritoneotomy, adequate dissection of the peritoneal reflection medially at the trocar insertion point is mandatory.

The following laparoscopic landmarks are useful for orientation in any retroperitoneoscopic renal procedure: the psoas muscle and posterior aspect of the kidney are identified first. This approach allows rapid visualization of the "vertically" oriented main artery and vein. To further facilitate exposure of the renal pedicle, save dissection of the anterior surface of the kidney to the last step. This will maintain retraction on the renal pedicle in case a nephrectomy or a partial nephrectomy is contemplated. In addition, this approach will suspend the kidney anteriorly, exposing the ureteropelvic junction in case a pyeloplasty is performed.

For identifying the renal hilum, we first locate the psoas muscle, and then find the great vessels medially, the aorta, or the vena cava; this may help to locate the renal hilum. On the right-hand side, initial identification of the inferior vena cava on the medial aspect of the psoas muscle facilitates identification of the gonadal, renal, and possibly suprarenal veins, which are located in the same plane. On the left-hand side, the pulsations of the aorta are often visualized and help guide the surgeon to the renal artery.

Transperitoneal Laparoscopic Approach

Transperitoneal procedures provide exceptional exposure since the intraperitoneal space is large.

Patient Preparation and Positioning

For upper transperitoneal procedures, positioning the patient in a flank or modified flank position at the edge of the table is crucial. This positioning allows the surgeon full access to the abdominal cavity without limitations caused by the edge of the table. For the modified flank, a roll should be placed under the torso to provide a 60° patient angulation from the table. The patient should be secured, so that the table may be repositioned as necessary during the procedure. The main monitor should be placed on the lesion side of the operative table, with a slave monitor behind the surgeon. All cables, lines, and wires for the instruments should preferably go off the opposite side to the surgeon. This positioning and port placement is used for the majority of renal interventions, such as nephrectomy, hemine-phrectomy, pyeloplasty, and other renal extirpative and reconstructive procedures. The transabdominal approach also allows access to the pelvis by altering the port use via placing the camera through the subcostal port and instruments through the umbilical and lateral ports.

For lower transperitoneal procedures in infants, it is most convenient to position the patient at the foot of the bed, across the bottom, and to stand at the side of the bed (at the patient's head) to operate. This is a good approach to the bladder. For older patients, a midtable, supine position with a sacral roll to thrust the pelvis up is preferable. Usually, the side opposite the lesion is chosen, and the telescope placed centrally in or near the umbilicus. The instrument trocars are placed lateral to the rectus muscle after insufflation, sufficiently superior and inferior to the telescope cannula so that the instruments can be introduced at a 45° angle relative to the operative field. The monitor should be located toward the foot end of the operative table. Only one monitor is necessary in this scenario. All cables, lines, and wires should be off the foot of the bed for optimal ergonomics.

This approach is extremely helpful for gynecologic and urologic procedures in the pelvis, including transvesical approaches. The new transvesical procedures, such as ureteral reimplantation, require cannula fixation so that the bladder mucosa does not strip and dissect away from the detrusor muscle. One way to achieve this is to perform a cystosomy at the skin incision to help hold the bladder wall and mucosa to the anterior abdominal wall. A balloon-tipped cannula may also be helpful here, but the size of the balloon tip may impair instrument manipulation in a small child.

Laparoscopic Technique

Transabdominal access is best achieved through the umbilicus using the open technique previously discussed, whereby the umbilical scar is lifted using an Allis clamp; then, using a #11 blade, the skin and subcutaneous tissue are incised and the peritoneum is entered.

Instruments can be placed directly through a stab wound without the need for a trocar if the surgeon does not anticipate repeatedly withdrawing and reinserting instruments through the site.

In infants and thin children, the laxity of the abdominal wall might allow large trocars or heavy instruments to compress the abdominal wall, obscuring vision and limiting CO_2 distention. Once access is attained, sometimes bowel, bladder, or other structures can obstruct the view. It can be helpful to pass one or more sutures through the abdominal wall, through the structure, and back out through the abdominal wall for retraction. These can be tied to a self-retaining retractor or can simply be tied at the distended abdominal wall if that is sufficient.

TECHNICAL LAPAROSCOPIC TIPS

Hemostasis

Vessels may be ligated with laparoscopic clip-applying devices that are available in 5 and 10 mm sizes. Laparoscopic tie-assisting devices are also available if clips are not preferable. They typically require a $\geq$5 mm cannula and either have a cinch knot technology or allow extracorporeal tying and knot placement with a pusher device. Freehand laparoscopic tying can also be performed, but is time-consuming and does not seem to be beneficial with the current hemostatic devices available.

Laparoscopic stapling devices are available for hemostasis. They are an excellent alternative for large vessels and for transecting thick tissue, such as bowel mesentery. The laparoscopic stapling devices require a ≥10 mm trocar for access and come in different lengths, deployment widths, and angulation capabilities. The tissue or vessel is transected as the staples are deployed. One must ensure that the device completely traverses the target before deployment; otherwise, hemorrhage can occur, especially with large vessels or thick vascular tissue. Stapling devices have been routinely utilized for main organ vessels, as well as mesentery, with reproducible success. If dividing vascular structures, one must be certain that the device contains vascular and not gastrointestinal staples.

There are three basic energy sources for hemostasis: monopolar, bipolar, and ultrasonic. The main difference between monopolar and bipolar modalities is that in monopolar surgery, the current goes through the patient to complete the current cycle, while in bipolar surgery, the current only goes through the tissue between the two electrodes of the instrument.

In monopolar surgery, electrical current created in the source unit passes through a single electrode to the tissue, causing the desired tissue effect almost exclusively near the electrode, since the density of electrons diminishes rapidly as the distance from the electrode increases.

To complete the cycle, however, the current needs to exit the patient, and will invariably choose the path of least resistance in seeking to return to an electron reservoir, such as the ground. Currently, most operating rooms use an isolated generator system with a dispersive electrode pad that is attached to the patient in relative proximity to the surgical site. This creates a set path for the current to exit the patient. The large surface area of the dispersion pad results in low current density at the attachment site, thereby minimizing the risk of skin burns. However, if the dispersion pad becomes loose with only partial skin attachment, the current density increases with the potential risk of skin burns. For maximum safety, the pad should be applied to well-perfused, dry, hairless skin over a large muscle and away from bone or metal.

Bipolar electrosurgery is generally performed at low voltage since tissue impedance is relatively low due to the proximity of the two electrodes. For this reason, these instruments are less effective for cutting tissue since adequate vaporization is difficult to achieve. The current travels from one electrode to another in a short distance. Typically, only the tissue in between the electrodes is affected by the current of energy. Different companies use bipolar energy with modifications, such as what is termed plasmakinetic, which allows cooling in between bursts of bipolar energy delivery to allow a greater amount of coagulation. Others employ nanotechnology with thermostats that give feedback on tissue properties to ensure better vessel sealing.

The ultrasonic cutting and coagulating surgical device converts ultrasonic energy into mechanical energy at the functional end of the instrument. A piezoelectric crystal in the handpiece generates vibration at the tip of the active blade at 55,500 times per second over a variable excursion of 50–100 μm. This results in rupture of hydrogen bonds and produces heat, which leads to denaturation of proteins and, eventually, separation of tissue. These effects are reached at tissue temperatures of 60°C–80°C, resulting in coagulum formation without the desiccation and charring caused by the temperatures of 80°C and higher associated with the traditional electrosurgical methods.

Light amplification by stimulated emission of radiation (laser) is a commonly used alternative to electrosurgery, and offers a precise application of energy without the inherent risks of lateral tissue damage and stray current associated with standard electrosurgery. Laser energy is generated when electrons jump from higher to lower energy levels during their circuits around the nucleus. The energy created induces molecular vibration and thermal energy upon contact with the target tissue. The most commonly requested laser, the "argon laser," in laparoscopy is not a true laser. It is an argon beam coagulator, which is a device consisting of an electrode recessed inside a probe through which argon gas is passed. The monopolar energy from the electrode is carried by the jet of argon, which is directed at bleeding tissue to cause hemostasis.

Care should be taken when dividing tissue or establishing hemostasis with high-energy devices, as injury to adjacent structures is possible. A 3–5 mm right-angled hook monopolar cautery is a useful device for dividing tissue and preventing hemorrhage. It is important to make contact with the tissue prior to activation of the monopolar electrocautery in order to avoid arcing of current, which may cause a delayed thermal injury to internal structures. Another form of electrocautery that is available is the 3 mm bipolar cautery forceps, which allows for greater control of the current than with standard monopolar cautery.

Suturing

Intracorporeal suturing requires two needle holders or a needle holder and a grasping device. Any length of suture, with its curved needle, may be directly passed through 5 mm trocars, but not through 3.5 mm trocars unless the curved needle is first straightened. The suture may also be passed through the abdominal wall to avoid the need for a 5 mm trocar if ≤3 mm trocars are utilized.

Laparoscopic extracorporeal-assisted tying is possible, but requires a large cannula at one of the port sites. There are a variety of automatic suturing devices; however, it is important for the endoscopic surgeon to become proficient with nonassisted intracorporeal suturing. Furthermore, the majority of devices have a limited choice of suture material size, and most are not acceptable for complex delicate reconstruction.

Tissue Extraction

The benign nature of most pediatric renal diseases allows specimen removal with little concern for spillage. In transperitoneal laparoscopic approaches, most structures can be extracted from the umbilical trocar site, whereas in retroperitoneal approaches, the site for the specimen extraction depends on its size. This includes segments of bowel, cysts, adrenal gland, biopsies, and nearly anything else compressible. In an infant, these tissues are brought directly through the trocar wound since there are few bags small enough to be of much use. In older children, if a 10 mm trocar is utilized, then endoscopic retrieval bags

may be utilized. Larger structures, such as intact solid kidneys or heminephroureterectomy specimens, may require enlarging a trocar incision to facilitate removal. The umbilical trocar site is typically utilized, or a small Pfannenstiel incision can be performed if it is convenient and remains inconspicuous.

Closure

The same technique is used for all laparoscopic procedures. For wounds of <3 mm, application of a tissue adhesive or adhesive paper strips is sufficient. Closing the fascia for all wounds of >3 mm in diameter is recommended. Fascial closure devices facilitate closure, especially in the obese patient.

POSSIBLE PITFALLS AND SOLUTIONS

Malfunction of the Equipment

Well-trained nurses capable of quickly recognizing and correcting equipment malfunction are mandatory. Since the success of the laparoscopic procedures depends heavily on the proper functioning of the equipment, these cases are best performed when skilled staff are available.

Fogging of the Lens

Initially warming the laparoscope in warm saline or povidone-iodine solution or using commercial defogging fluid may help clear the lens and improve the image. Inadequate vision, on the other hand, may result from a gas leak around the primary trocar. This usually leads to complete collapse of the retroperitoneal space, and an extra purse-string suture around the trocar may help to decrease the leak. Another possible reason for inadequate vision during retroperitoneoscopy is a peritoneal tear causing intraperitoneal insufflation. It is then necessary to either convert to a transperitoneal laparoscopic approach or attempt venting the peritoneum using the technique described below. Whether a patient has undergone retroperitoneal surgery before or not, dissection of a previously inflamed retroperitoneum may be suboptimal and frustrating and also dangerous; hence, conversion to open surgery may be considered at any time and should not be considered a failure. Families must be aware of this possibility.

Bleeding

Bleeding may occur while bluntly dissecting, especially the retroperitoneal space; in this case, posterior secondary trocars should be placed and the small vessels must be handled carefully using electrosurgical scissors or the bipolar cautery forceps to secure hemostasis.

Subcutaneous Emphysema

Subcutaneous emphysema may occur due to leakage of CO_2 into the skin around the area of the ports, as the area is larger than the size of the trocar. Signs of this problem include readily palpable crepitus over the flank and abdomen. Treatment for this complication includes either placement of a purse-string suture around the leaking port, changing the trocar to a larger size, or reduction of the insufflation pressure.

Intraperitoneal CO_2 Insufflation during Retroperitoneal Laparoscopic Surgery

If this insufflation occurs prior to the insertion of the two 5 mm accessory trocars, consider transperitoneal or open conversion.

If this insufflation occurs while inserting the secondary trocars (mainly the medial one, superior to the iliac spine), then consider insertion of a Veress needle or an angiocath at the level of the umbilicus intraperitoneally to deflate the peritoneum and change the site of secondary trocar insertion. Since there is intraperitoneal CO_2 insufflation, the risk of injury to the bowels with the Veress needle or angiocath is minimal.

POTENTIAL COMPLICATIONS

Laparoscopic surgery always carries the risk of inadvertent injuries, more common during the learning curve, and increasing experience may lead to a decrease in the complication rates. Since most of the injuries occur during blind access maneuvers with a Veress needle or trocars, the open technique is recommended. Generally, complications that may occur in laparoscopic urological procedures are dependent on the organ operated on.

Great vessel injury may occur from laparoscopic access or dissection. *In children, the distance between the abdominal wall and the great vessels may be as little as 5 cm.* To avoid vascular injury secondary to access, it is advisable to tailor the length of the trocars to the patient age and body habitus. The hallmark features of vascular injuries include either bloody return from the injury site or rapid deterioration of the hemodynamic status of the patient. Once extensive vascular injury is suspected, the trocar should be left in place and an open exploration should be performed. If minor vascular injury is encountered during dissection, such as laceration to the gonadal vessels or adrenal vessels, hemostasis can potentially be achieved laparoscopically through the use of the clips, staples, or ligation.

Bowel injury is a risk of both transperitoneal and retroperitoneal laparoscopy. Because the bowel is out of sight during retroperitoneal procedures, injuries may occur during trocar insertion or dissection secondary to lacerations or thermal injuries from electrocautery. If bowel injury is identified during laparoscopy, it is best dealt with at the time of occurrence. If the surgeon is laparoscopically skilled, the bowel may be repaired using a laparoscopic approach; otherwise, a general surgery consult is recommended. Delayed presentation of bowel injury may occur, and in order to differentiate ileus from bowel injury, a high clinical suspicion should be present. For instance, localized pain at the trocar site associated with fever and leucopenia may be a manifestation of bowel injury.

Furthermore, patients with high suspicion of bowel injury should undergo imaging to rule out gas under the diaphragm, although this can be confusing early on, as CO_2 might persist from insufflation.

We believe that a contaminating injury to the small or large bowel is best handled by open repair with or without proximal fecal diversion. In addition, injuries to the liver or spleen may occur while performing laparoscopic retroperitoneal surgery. If the injuries are superficial, attempts to control the injury laparascopically with gel foam or with an argon beam coagulator may be undertaken; also, open exploration is recommended. Since these injuries may go unnoticed, inspecting the peritoneal or retroperitoneal space upon access and prior to exiting is of paramount importance.

Finally, port-site herniation may occur in 3 and 5 mm trocar sites. Most of the time, it is the omentum that herniates through the port site. This usually requires taking the patient to the operating room for definitive management. A few published reports state that 3 and 5 mm trocar sites should be closed; however, no definitive algorithm exists. It is at the discretion of the surgeon whether closure of these wounds is warranted. Nonetheless, since trocar site closure in the pediatric patient is relatively straightforward, one should consider it in order to prevent the potential complication of herniation. Our approach has been at all times to attempt to close trocars that are larger than 3 mm.

CHAPTER 12

Pediatric Fluid Management

William Waldrop and Jake Christensen

INTRODUCTION

Appropriate and well-designed fluid management strategies have been shown to significantly impact patient outcomes from surgical intervention. Indeed, the science of evidence-based fluid administration has advanced considerably in the last 50 years since the publication of the seminal paper by Holliday and Segar.[1] Protocol-based fluid therapy has been shown to impact the incidence of cardiopulmonary events,[2] duration of hospitalization,[3] wound healing, and bowel motility,[2] in addition to its known effect on postoperative nausea and vomiting.[4]

The notion of manipulating fluids to treat patients was first advocated during the cholera epidemic in Britain during the 1830s.[5] A 22-year-old medical graduate, William O'Shaughnessy, described the common practice of bloodletting with emetics as potentially harmful, and reported in the *Lancet* the loss of "neutral saline ingredients" upon chemical analysis of the blood.[6] Shortly thereafter, Thomas Latta published the first successful intravenous resuscitation of a moribund woman with cholera in a graphically descriptive case report.[7] The patient went from pallid and near comatose to awake and fully conversant within 30 minutes after aggressive treatment of hypovolemic shock. Despite these early successes, parenteral saline therapy was not widely used for another half century.[5]

The goal of perioperative fluid management is to maintain the intrinsic homeostasis of the human body. This homeostasis is constantly threatened by the surgical experience, whether by acute blood loss, hypothermia, or the body's response to stress. An elegant plan combines the goals of the individual patient's condition with the expected intensity of the surgery.

Fluid management of pediatric patients is further complicated by several factors. These include age-related differences in metabolism, organ maturity, and body compartment volumes. The incidence of iatrogenic hyponatremia, for instance, is unquestionably higher in the neonatal population, given these differences, and can lead to significant morbidity, including cerebral edema and death in healthy patients.[8]

This chapter provides a brief overview of normal fluid and electrolyte homeostasis throughout the perioperative period, with special attention to the differences between neonates and older children. Various options for volume replacement are described, including special situations requiring elucidation, such as blood component therapy and emergent resuscitation. The aim of this chapter is to provide the basic framework for perioperative fluid management of the pediatric patient.

FLUID AND ELECTROLYTE MANAGEMENT

Developmental Considerations

The greatest challenges in determining the appropriate replacement fluid in pediatric patients occur during the first year of life. Because of several age-related changes, including higher metabolic rate, organ maturity, and subsequent fluid compartment volumes, the first year of life does not lend itself to the generation of simple formulas, unlike in older children and adults.

Considering the immense energy requirements of the developing brain and the brain's large size relative to the infant's body, the basal metabolic rate of preterm and term infants is much greater than that of a child per kilogram of body weight. The basal metabolic rate is the amount of energy per unit time required to power the human body at rest. In preterm infants, this rate has been calculated at 58 kcal/kg/24 hours; the respective values for term and 2-week-old infants are 32 and 48 kcal/kg/day.[9] This rate is roughly increased three- to fourfold over the child and adult value of 15–20 kcal/kg/day. The basal metabolic rate also does not include the energy requirements for growth, which persist throughout puberty and are highest in the first year of life.

Similarly, the infant is challenged because of organ immaturity. The gastrointestinal tract has a diminished capacity for nutrient absorption, as evidenced by the rapid transit time for formula and breast milk. Likewise, the immaturity of the liver cannot support the formation of glucose in the fasting state (gluconeogenesis), which has direct effects in the perioperative period. Most notably, the immature kidneys have both diminished activity (renal blood flow and glomerular filtration rate) and the inability to concentrate urine effectively (due to suboptimal osmolar gradients). Functionally, this results in greater water loss, although this problem is somewhat ameliorated by increased antidiuretic hormone (ADH) secretion with major surgery. The issue of urine concentration becomes less acute by 3 months of age, given the rapid development of sodium concentration gradients.

Electrolyte Requirements

Sodium and potassium are the major osmotically active cations in the body, with sodium predominating the extracellular space, and potassium the intracellular fluid compartment. Counteracting the electrical charge, chloride and bicarbonate are the major anions within the extracellular space. The homeostasis of electrolytes at the cellular level is tightly regulated by active cellular pumps and passive diffusion of free water, which maintains the concentration gradient essential for cellular function.

Physiologic losses of sodium, potassium, and chloride occur by renal excretion. Bicarbonate is the primary acid–base buffer in the extracellular fluid. Pathologic conditions that might interrupt homeostasis for sodium and chloride include active losses in the gastrointestinal tract (diarrhea or vomiting), pleural effusions, or ascites.[10] As "water follows salt," the primary electrolytes of concern for fluid management are sodium and chloride, which determines the major component of osmotically active material in the extracellular fluid, and hence the intravascular volume. Likewise, the total body potassium concentration is critical to normal cellular functions, most notably the electrical activity of the heart and muscle contraction.

The daily maintenance requirements for sodium chloride and potassium are 3 and 2 meQ/100 cal/day, respectively, in children.[11] These requirements were first described in the paper by Holliday and Segar in 1957,[1] and have stood the test of time remarkably well. The commonly used maintenance fluid D5 1/2 normal saline plus 20 meQ/L potassium chloride is based on these daily electrolyte goals.

Free Water Requirements

The utilization of water by the body directly reflects the metabolic rate. As described above, preterm and term infants therefore have a much greater requirement at baseline for free water. In addition, pathologic states that might increase the metabolic rate (e.g., hyperthermia, infection, and cardiac exercise) will dramatically increase the amount of excess free water required to maintain the intravascular space, the ultimate goal in perioperative care. Water can also be "lost" by increased sweat (fever), stool (diarrhea or vomiting), or insensible losses (evaporative loss from an open abdomen). Functional loss of water by sequestration in the cellular interstitium, commonly known as "third spacing," occurs during inflammatory insults, such as surgery or sepsis, and renders the fluid incapable of organ function, such as oxygen delivery by cardiac output or waste removal by the kidneys.[11] Fortunately, if monitored appropriately, most of these variables are within the control of the team caring for the patient.

The production of 1 cal of energy requires net consumption of 1 mL of water by definition. The requirement for free water is therefore a direct expression of the metabolic rate. The basis for daily caloric requirements was elucidated by Holliday and Segar in 1957,[1] and remains the foundation for hourly maintenance calculations. In this landmark study, the investigators plotted caloric requirements in healthy, hospitalized patients at rest, and discovered three linear relationships based on weight. The first 10 kg of infants and children required the highest supplementation, 100 cal/kg/day. Older patients required an additional 50 cal/kg/day between the weights of 10 and 20 kg, and an additional 20 cal/kg/day for each kilogram from 21 to 70 kg. Divide these numbers by 24 hours in a day, and one arrives at the simple formula for hourly maintenance fluid requirements (4 mL/kg/hour for the first 10 kg, 2 mL/kg/hour for the next 10 kg, and 1 mL/kg/hour for above 21 kg—the 4/2/1 rule; Table 12.1).

TABLE 12.1 Hourly (4/2/1 rule) and daily maintenance fluids according to child's weight

Weight	Hourly fluid requirements	Daily fluid requirements
<10 kg	4 mL/kg	100 mL/kg
10–20 kg	40 mL + 2 mL/kg Above 10 kg	1000 mL + 50 mL/kg Above 10 kg
>20 kg	60 mL + 1 mL/kg Above 20 kg	1500 mL + 25 mL/kg Above 20 kg

Interestingly, Lindahl in 1988 used indirect calorimetry to determine the basal metabolic rate in children under general volatile anesthesia.[12] Given the known effects of metabolic suppression of the brain, liver, heart, and kidney during general anesthesia, it was perhaps unsurprising that energy expenditure was 50% lower than the basal rate calculated by Holliday and Segar.

There are currently no effectively reliable monitors that can describe a patient's intravascular volume status. Despite many attempts to link central venous pressure, pulmonary capillary wedge pressure, and transesophageal Doppler to intravascular status,[13] none of the technologies has proved statistically superior. Instead, the mainstay of intravascular assessment remains clinical. In the appropriate clinical milieu, vital sign analysis and fluid responsiveness (the patient's response to fluid bolus) are the clinical determinants of normal intravascular status. Also, the urine output can be assessed on an hourly basis to ensure adequate preload for end-organ function (>0.5 mL/kg/hour should be targeted during surgery).

Glucose Management

There are many known risks for both hypo- and hyperglycemia during an operation. The risks of both are compounded during general anesthesia, as neither can be diagnosed without clinical suspicion in the anesthetized patient. Hypoglycemia carries the known risk of seizures and brain damage, especially in the vulnerable neonatal population.[11] Evidence suggests a very low incidence of hypoglycemia in the perioperative period (<1%) despite prolonged fasting and the majority of patients not receiving intraoperative dextrose.[14] The exception to this rule appears to be neonates, whose minimal liver glycogen stores place this patient at exceptional risk for hypoglycemia. A 1% dextrose solution with lactated Ringer's is emerging in the literature as an appropriate solution to provide neonates with a glucose floor, targeting euglycemia with a glucose level of 65–120 mg/dL.[15] Glucose given

at 120–300 mg/kg/hour maintains an acceptable blood glucose level and prevents lipid mobilization in infants and children.[11]

Intraoperative infusions of dextrose-free isotonic solution should be routine for older children for most procedures. The stress response from surgery will lead to an increase in blood glucose levels in most patients, which tends to correct within 2–3 hours of surgical incision. Persistent hyperglycemia can induce an osmotic diuresis, placing the patient at risk for dehydration and electrolyte disturbances if not closely monitored. Animal studies also favor hypoxic-ischemic brain and spinal cord injury with prolonged hyperglycemia.[16] Frequent laboratory monitoring of glucose level is the only way to avoid these complications.

FLUID COMPARTMENTS

Total Body Water

The human body is composed mostly of water, ranging from 80% of body weight in the preterm infant to around 60%–65% by a child's first birthday. The water fraction of body weight remains remarkably consistent through adulthood at around 60%. Total body water (TBW) can be thought of conceptually as divided between intracellular fluid and extracellular fluid (Figure 12.1). The infant has an excess of extracellular fluid relative to an older child, supporting a larger fraction of intravascular volume. As the child grows, the intracellular component becomes more prominent, as cellular mass expands, including fat cells and muscle.

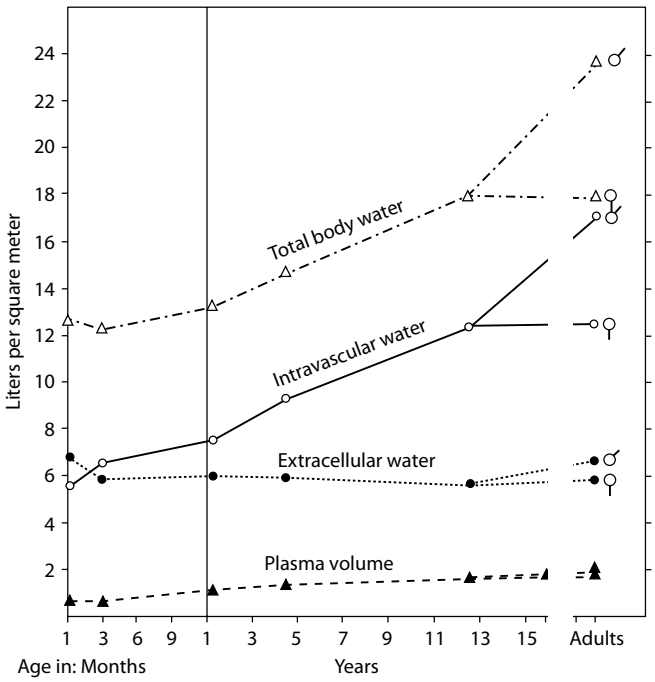

FIGURE 12.1 Changes in TBW, extracellular water, intracellular water, and plasma volume in liters per square meter in infants and children and the corresponding values in adults.

Extracellular Fluid

Extracellular fluid can be further subdivided into transcellular fluid, interstitial fluid, and intravascular volume. The transcellular fluids constitute a minor portion of the extracellular compartment, around 1%–3% of body weight. This includes cerebrospinal fluid, pleural and peritoneal fluids, gastrointestinal secretions, synovial fluid, and the aqueous and vitreous humors of the eyes.[17]

The interstitial component is high in term babies, at around 45% of TBW. By adolescence, this drops to around 20%. The importance of the interstitium in fluid management cannot be overstated. Because the interstitium rapidly equilibrates electrolytes and water with the intravascular space, the interstitium becomes an important reservoir for fluids given to the patient. During surgical stress and sepsis, the interstitium becomes the "third space," expanding in potential volume to be mobilized after the stress has abated several days later.

Intravascular Volume

The most critical space to understand in children is the intravascular volume. Because of an infant's high ratio of body surface area to weight and increased metabolic rate, the intravascular volume is increased for compensation. The normal term newborn has a blood volume of 90 mL/kg. As the child grows and becomes more proportional to weight, the blood volume decreases to 80 mL/kg by 10 years of age. Adolescents and adults have an average circulating blood volume of 65 mL/kg.[18] These calculations have important implications for dosing blood products, as discussed below.

FLUID REPLACEMENT SOLUTIONS

Crystalloid Solutions

There is an increasingly complicated list of fluids to choose from to administer to patients. Understanding the basic composition of these fluids will help the physician decide which of them should be administered. Crystalloids are classified according to how closely they approximate the osmolarity of the extracellular compartment: hypotonic, isotonic, and hypertonic. The pediatric population has a mean serum osmolarity of 284.2 ± 6.9 mOsm/dL.[19] Crystalloid fluids have the basic composition of electrolyte salts dissolved in sterile water. By varying the electrolyte composition, the tonicity of the fluid changes as well (Table 12.2). Tonicity refers to the portion of total osmolarity that has the potential to induce transmembrane water movement.[20]

Hypotonic

The osmolarity of a hypotonic solution is less than that of the extracellular fluid compartment. More than half a century ago, Holliday and Segar[1] calculated daily free water requirements, energy expenditure, and daily electrolyte requirements. Historically, the use of hypotonic maintenance fluids attempted to replace normal hourly expenditures and is not meant as a volume expander or for deficit replacement. Using these fluids as volume expansion places

TABLE 12.2 Crystalloid solutions

Solution	mmol/L						
	Na	Cl	K	Dextrose	Ca	Lactate	Osmol
D5W				50 g/L			252
D3.3/0.3% sodium chloride	51	51		33 g/L			269
D5/0.2% sodium chloride	34	34		50 g/L			321
D5/0.45% sodium chloride	77	77		50 g/L			406
0.9% sodium chloride (normal saline)	154	154					308
Lactated Ringer's	130	109	4		104	28	272
Lactated Ringer's with 5% dextrose	130	109	4	50 g/L	104	28	524
3% sodium chloride	513	513					1027

the patient at significant risk of hyponatremia, as well as dilution of other electrolytes. An ongoing controversy exists regarding the best composition for maintenance fluids. When determining the proper solution to administer, careful thought as to the patient's requirement of water, salt, and glucose should be undertaken. A 5% dextrose in water solution is hypotonic, but has an osmolarity that approximates plasma. This osmolarity therefore prevents the hemolysis that would occur with an infusion of pure water.[21]

Isotonic

Isotonic fluids, such as normal saline and lactated Ringer's, approximate the osmolarity of the extracellular compartment. Normal saline is a saltwater solution and is composed by dissolving 9 g of sodium chloride into 1 L of sterile water to produce 0.9% sodium chloride solution. These fluids are widely used for expansion of the extracellular compartment, deficit replacement, or rehydration. As isotonic fluids do not change the extracellular/intracellular osmotic gradient, no net fluid shift occurs. Isotonic crystalloid fluid added to the vascular compartment is quickly redistributed between the intravascular and interstitial compartment. This can lead to significant tissue edema.

Hypertonic

Hypertonic fluids, for example, 3% sodium chloride, are hyperosmolar relative to plasma. In addition to expanding the intravascular compartment, they will expand the extracellular volume and increase its osmolarity, thereby changing the extracellular/intracellular osmotic gradient. For this reason, a free water shift from the intracellular to the extracellular compartment will occur. The indications for this fluid are limited, and the volume administered should be relatively small. The most well-known indication is for traumatic brain injury, as 3% sodium chloride can reduce brain edema and lower intracranial pressure. Hypertonic saline has also been studied in situations of massive hemorrhage, given the desire to stabilize intravascular volume but minimize further bleeding with higher blood pressures.[22]

Colloid Solutions

Colloid solutions are composed of large relatively impermeable molecules that exert intravascular osmotic pressure in order to expand the intravascular space. Colloid solutions are designed to remain intravascular and not to equilibrate to the interstitial compartment. However, in pathologic states, such as surgery, capillary leakage of these fluids does occur.[23] For these reasons, colloids should not be used as maintenance fluid for insensible losses but for volume expansion to replace acute blood loss. Examples of colloid solutions are the following: starches, albumin, and gelatins.

Starches

Naturally occurring starches are rapidly metabolized by amylase in the plasma. Hydroxyethyl starch (HES) is a synthetic colloid modified from naturally occurring starches and is highly resistant to metabolism. HESs are available in differing concentrations (3%, 6%, and 10%) and differing molecular weights (low, <70 kDa; medium; and high, >450 kDa). The C2:C6 hydroxyethylation substitution results in prolonged duration of action without increasing the known side effects. For this reason, the newer generation of HES has a high C2:C6 ratio but low molecular weight.[24] Side effects of HES include its anticoagulant effect (with volumes greater than 1.5 L in adults), potential to worsen renal function, and pruritis resistant to therapies in up to 22% of patients.[24]

Albumin

Albumin is derived from pooled human plasma and is osmotically equivalent. It remains the standard colloid administered in infants and neonates. Albumin has a molecular weight of 69 kDa. Allergic reactions are possible but significantly reduced in comparison with the other colloid solutions.[25] Albumin has been shown to have higher mortality than saline when administered as acute resuscitation to critically ill traumatic brain injury patients.[26]

Gelatins

Gelatins are polypeptides produced by degradation of bovine collagen. While use in Europe is common, no gelatins are currently available in the United States due to the highly allergic propensity of initial preparations.[24] Gelatins are a less effective colloid, having the relatively

small molecular weight of approximately 35 kDa. The benefits of using gelatins for volume expansion include rapid degradation with renal clearance, allowing proponents to maximize volume expansion within the intraoperative period.[24] Their efficacy in infants is in doubt; a Cochrane review of preterm infants found gelatins to be equal to no fluid therapy when assessed for necrotizing enterocolitis.[27]

PERIOPERATIVE FLUID MANAGEMENT

Preoperative Fasting

Fasting guidelines are for the purpose of reducing the risk of regurgitation in the unconscious state and subsequent pulmonary aspiration. Excessive fasting times can have deleterious effects, such as decreased intravascular volume, hypoglycemia, hunger, irritability, and dissatisfied parents. Current well-established guidelines allow clear liquids up to 2 hours prior to anesthesia in the otherwise healthy pediatric patient.[28] Other guidelines are as follows:

- 2 hours after clear liquids
- 4 hours after breast milk
- 6 hours after infant formula or nonhuman milk
- 6 hours after a light meal
- ≥8 hours after a full meal

In the healthy infant or child, these guidelines will have minimal physiologic or metabolic effects. Decreased fasting times will improve intravascular volume, leading to a more stable induction of anesthesia and ease in obtaining vascular access. Chewing gum has been shown to significantly increase gastric volumes above controls.[29] If gum has not been swallowed, providers treat this as a clear liquid and impose a 2-hour restriction. In children who have undergone trauma, gastric transit times are reduced and unpredictable, and there is no safe fasting time.[28]

Preoperative Fluid Therapy

Healthy outpatients who have followed the fasting guidelines outlined do not require preoperative fluid administration. Venous access can be delayed until induction of anesthesia in many of these healthy young patients. However, there are still patients who will not fit these criteria. Dehydration can arise from many clinical scenarios, such as prolonged fasting, vomiting, diarrhea, sepsis, burn patients, and diabetes. The accurate assessment of fluid status will guide fluid management throughout the perioperative course. Presenting history that supports dehydration includes recent vomiting or diarrhea, decreased urine output (i.e., number of wet diapers), decreased oral intake, decreased activity level, and acute weight loss. During physical examination, the providers can assess for skin turgor and capillary refill time, abnormal respiratory pattern, dry mucous membranes, sunken fontanelle, sunken eyes, weak pulse, increased heart rate, cool extremities, and overall appearance. Laboratory data supporting dehydration include an elevated bun/creatinine ratio, the presence of acidosis with a low bicarbonate value, and an anion gap. In a review of the literature, Steiner et al. found capillary refill time, skin turgor, and abnormal respiratory pattern among the best signs to predict dehydration on examination.[30] Making the accurate diagnosis of dehydration and estimating its severity will require taking all available clinical information into consideration.

Restoring intravascular volume is essential in the preoperative patient. Isotonic fluids, such as normal saline or lactated Ringer's, should initially be used when replacing acute fluid deficits. Maintenance fluids are handled differently. In children, daily sodium and potassium requirements are 2–4 mmol/kg each, which when combined with daily fluid requirements results in a hypotonic solution.[11] Historically, fluid administered as maintenance by pediatricians is D5 1/4 normal saline with 20 mEq/L KCl.[31] The hourly maintenance fluid requirement, the Holliday–Segar method, is described above and based on caloric expenditure calculated from weight.

Infants and young children have reduced glycogen stores. For those at risk of hypoglycemia, a dextrose-containing IV fluid should be administered during the fasting period and extended throughout the operative course until baseline feeds can be reestablished. For those patients who are fasting for prolonged periods of time, total parenteral nutrition (TPN) should be considered. When stopping TPN perioperatively, a dextrose-containing fluid with a similar glucose infusion rate should be started to avoid hypoglycemia.

Intraoperative Fluid Management

Intraoperative fluid losses are primarily isotonic, and therefore are replaced differently from the hypotonic fluids typically used preoperatively for maintenance. Fluid replacement intraoperatively takes into account the maintenance requirements from the fasting period, surgical blood loss, third-space fluid loss, and insensible fluid losses, including that from the surgical field by evaporation. In addition, the surgical stress response promotes an increased secretion of ADH. This increased ADH response results in water resorption in the distal renal tubules and collecting ducts.[32] This free water retention from the increased ADH response, combined with the potentially large isotonic surgical losses, places the patient at risk of hyponatremia if the replacement fluid used is hypotonic with respect to blood.

Published rates of third-space fluid loss vary among operations performed. These losses can be as low as 1 mL/kg/hour for very minor surgical procedures to as much as 15–20 mL/kg/hour for major abdominal procedures, or even as much as 50 mL/kg/hour for necrotizing enterocolitis in premature infants.[11] Younger patients have a larger extracellular fluid volume (45% body weight for neonates vs. 20% for adults), which creates more opportunity for equilibration and third-space loss. Isotonic crystalloid fluids equilibrate across the extracellular fluid compartment. Normal saline is actually slightly hypertonic with an osmolarity of 308 mOsm/L; it is comprised of a sodium concentration of 154 mEq/L and a chloride concentration of 154 mEq/L. When using normal saline for volume expansion in large amounts, a hyperchloremic metabolic acidosis can result. This is due to the normal

saline providing excessive chloride, causing a shift in the strong ion difference (which is one of the main contributors to the standard base excess).[33] Lactated Ringer's actually causes a slight base excess, as it contains lactate that is metabolized to bicarbonate in patients with normal liver function. Lactated Ringer's solution is actually slightly hypotonic with an osmolarity of 273 mOsm/L and has a sodium concentration of 130 mEq/L. When using lactated Ringer's for volume expansion, the perioperative risks of hyponatremia should also be considered.[34]

When acutely volume resuscitating with isotonic crystalloid solutions, an initial bolus of 10–20 mL/kg is usually given, and then cardiovascular stability is reassessed. After reaching 30–50 mL/kg of crystalloid solution, the use of colloid solution (albumin or synthetic colloid) to maintain intravascular osmotic pressure is indicated.[11] Hetastarch is more controversial than albumin, and among pediatric anesthesiologists, it is avoided in the premature and newborn infant.[11] Hetastarch at large volumes has an anticoagulant effect; at volumes greater than 20 mL/kg, it has been demonstrated to increase the prothrombin time.[35] Blood loss is replaced in a three-to-one volume with crystalloid solutions due to its equilibration across the extracellular compartment, while colloids and blood products are replaced in a one-to-one fashion with blood loss.

Blood Component Therapy

Volume resuscitation with isotonic and colloid solution in the bleeding patient is performed until the decision to transfuse is reached. This decision should be collaboratively discussed between the surgeon and anesthesiologist, as there is no empirical evidence to support a transfusion trigger. Indeed, the decision to transfuse needs to be made based on overall assessment, and should include consideration of the hemodynamic status, extent of ongoing blood loss, disease severity, comorbidities, and lactate and mixed venous oxygen saturation, if available, among other considerations.

In order to make this determination, and the amount of blood products to transfuse, it is necessary to calculate the estimated blood volume (EBV). The EBV is calculated based on the age and weight of the child (Table 12.2).[32] Knowing the allowable blood loss (ABL) will help in making the determination to begin blood component therapy. ABL is calculated as follows (Table 12.3):

$$\text{ABL} = \frac{(\text{Starting hematocrit} - \text{Lowest allowed hematocrit})}{\text{Starting hematocrit} \times \text{EBV}}$$

TABLE 12.3 Estimated circulating blood volume versus age or weight

Age	Estimated blood volume (mL/kg)
Premature infant	90–100
Term infant to 3 months	80–90
Children older than 3 months	70
Very obese children	65

Neonates and infants have a higher ratio of oxygen consumption to blood volume than adults, and the neonatal myocardium works at near maximal levels at baseline. For this reason, the newborn heart may not be able to compensate for a decreased oxygen-carrying capacity by increasing cardiac output.[36] Neonates and infants may also have reduced ability to oxygenate blood due to the presence of cardiac or lung disease. The neonate and infant may benefit from maintaining a higher hematocrit (Hct) for these reasons.[37] It is important to know that one unit of packed red blood cells (PRBCs) is approximately 250 mL and has an Hct that approximates 70%. The usual starting dose is 10 mL/kg, which is expected to raise the Hct by 9%. In order to calculate the volume of PRBCs to administer based on the estimated blood loss (EBL) beyond the ABL, the following formula[37] can be used:

$$\text{Volume of PRBCs to transfuse} = \frac{(\text{EBL-ABL}) \times \text{Target Hct}}{\text{Hct in PRBCs (70\%)}}$$

Blood components are typically used rather than whole blood. This can be more cost-effective, as a single donor unit of blood is split into components and made available to multiple patients. Whole blood contains all clotting factors; therefore, when using component therapy during a massive transfusion situation, care must be taken to prevent a dilutional coagulopathy from occurring. Fresh frozen plasma (FFP) contains 250 mL of plasma in a citrate anticoagulant. FFP at 10 mL/kg raises most factors by 10%, and the fibrinogen level will rise 40 mg/dL when 15 mL/kg is given.[38] An apheresis unit of platelets contains 3×10^{11} platelets in 250–300 mL of plasma. A dose of 10 mL/kg can increase the platelet count by 20,000–50,000.[38]

Many complications can arise during blood component therapy. During massive transfusion when multiple PRBCs have been given, clotting factors will become diluted unless administered concurrently. As a general rule, the platelet count will be decreased by 40% after loss of one blood volume, and by three blood volumes lost, it will be decreased by 70%, assuming no replacement.[37] All blood products contain citrate as a storage anticoagulant. FFP has a considerable amount of citrate, and when given rapidly, it can lead to a reduction in ionized calcium and hypotension. In addition, patients with decreased liver function and neonates are at risk of hypocalcemia and citrate intoxication due to decreased metabolism.[36] Normal saline should be used as the carrier when transfusing blood products, as the calcium in lactated Ringer's may lead to microaggregation and calcium deposition. Care must be taken by the transfusionist to prevent ABO incompatibility, which can result in an acute hemolytic reaction.

Blood transfusion therapy can also lead to transfusion-related acute lung injury (TRALI), transfusion-associated circulatory overload (TACO), and transfusion-associated graft versus host disease (TA-GVHD). TA-GVHD has particular importance in pediatrics and occurs when donor lymphocytes proliferate and cause host tissue destruction.[36] This is mostly a concern in the immunocompromised recipient who cannot mount an immunologic response to donor lymphocytes, such as those with

primary immunodeficiency (e.g., severe combined immunodeficiency, Wiskott–Aldrich syndrome, and DiGeorge syndrome), as well as prematurity, acute blood loss, cardiopulmonary bypass, and neonatal stress.[39] TA-GVHD can occur in the immunocompetent patient who receives blood donated from a biological relative. The related donor lymphocytes may not be recognized as foreign due to their similar haplotypes, and the recipient does not mount an immune response; therefore, the donor lymphocytes proliferate and destroy host tissue.[36] Irradiation of donor units effectively inhibits lymphocytes from proliferating and preventing TA-GVHD; therefore, it should be employed whenever TA-GVHD is a risk.[39]

Emergent Volume Resuscitation

During emergent volume resuscitation, the choice of fluid, volume, and rate of administration varies depending on many clinical variables. Early volume resuscitation is initiated with boluses of 10–20 mL/kg titrated to adequate blood pressure, heart rate, quality of peripheral pulses, capillary refill, peripheral temperature, level of consciousness, and urine output.[40] In septic shock, the volume and rate of vascular loading has prognostic significance; in general, the younger the child, the greater the volume of fluid loading to body weight.[11] If patients do not respond to this initial therapy, consideration for invasive monitoring to guide therapy should be given. In the instance of trauma with ongoing blood loss, volume resuscitation should be managed in order to minimize the lethal triad of hypothermia, acidosis, and coagulopathy.[41] Institutional use and availability of massive transfusion protocols significantly reduces the amount and cost of the blood components used.[42] Recent studies of massive transfusion in combat trauma with life-threatening hemorrhage have been associated with decreased mortality with the earlier use of hemostatic blood products. Emerging literature suggests transfusion at a 1:1:1 ratio of PRBCs to FFP to platelets.[43]

Postoperative Fluid Management

In most instances of day surgery, the postoperative pediatric patient will be allowed to take fluids by mouth within the first few hours. When oral intake is not allowed, such as with bowel surgery, then intravenous fluid therapy must resume. Isotonic fluids are recommended in the postoperative period, as hyponatremia is the most common electrolyte disorder. Prepubertal children are more susceptible to perioperative hyponatremia, which can occur after elective surgery and can cause severe hyponatremic encephalopathy, resulting in death or permanent brain damage.[44] Increased ADH secretion during surgery and administration of hypotonic solutions can lead to a state of hyponatremia, which patients remain at risk for in the postoperative period. Signs of cerebral edema include decreased consciousness, disorientation, vomiting, and in severe cases, seizure activity refractory to antiepileptics.[11] By using isotonic solutions in the operative and postoperative period, hyponatremia and its severe consequences can be prevented.

SUMMARY

Fluid therapy in the pediatric patient requires careful consideration of the patient's developmental stage. Changes in metabolism, organ maturity, and fluid compartments pose additional challenges. Crystalloid, colloid, and blood component therapy should be used thoughtfully and with evidence of patient need. Laboratory reevaluation is encouraged to assist in achieving homeostasis and improved patient outcomes.

CHAPTER 13

Problems with Transitional Care

Dan Wood

CASE 1: CONCERNS WITH PENILE APPEARANCE IN EXSTROPHY

You receive a new referral to your clinic of a 17-year-old boy born with bladder exstrophy. He has had many previous operations, but 5 years ago, in order to achieve continence, his pediatric urology team created a continent urinary diversion and augmented his bladder with an ileocystoplasty. He is dry and happy with no apparent urological issues (you can assume his follow-up for this is dealt with). However, during your consultation he expresses concern about his penile appearance in relation to size and his ability to have penetrative sexual intercourse with a partner. He also tells you that he has had three attacks of epididymitis in the last year.

Questions

1. How would you begin to assess his penile function? What questions would you ask? How could you investigate him?
2. What are the anatomical limitations in reconstructing an exstrophy penis?
3. On further investigation, you discover a marked dorsal chordee. What are your operative options? What major risks would you explain to the patient?
4. What are the concerns relating to the urethra? How would you manage these?
5. Why do you think he has suffered epididymitis? How would you address this?

Discussion

1. It is vital to take a thorough sexual history as a baseline. This needs to include whether he has attempted penetrative intercourse, and if so, was he able to achieve that with a partner? For some, the reconstructive result is excellent and they need reassurance that they can and will go on to have good relationships on both an emotional and a physical level. You need to document whether he currently achieves normal erection, orgasm, and ejaculation. Ejaculation in bladder exstrophy may be limited for two reasons. The first may be that the bladder neck surgery may have caused damage or obstruction to the ejaculatory ducts, resulting in a reduction in ejaculate volume. The second issue is the absence of the propulsive bulbocavernosus muscle that creates the propulsion seen in normal ejaculation. It is also important to ask him about the shape of his penis when erect. One corpora may be more scarred than the other, creating a curvature, or it is common to see a very severe dorsal chordee with the penis parallel to the abdominal wall—making intercourse impossible. Depending on the outcome of your discussion, you may recommend an artificial erection (discussed in the next section) or imaging—an MRI may be helpful if operative intervention is planned.
2. Aside from previous surgical interventions, it is important to understand that the exstrophy penis has corpora that are up to 50% shorter than those of a normal penis. This is important in counseling patients, as the exstrophy penis is typically shorter and wider than normal, and no surgery is going to change that to a "normal" situation. A wide pubic diastasis may compound this impression. The neurovascular bundles are commonly more laterally placed in the infant exstrophy penis, but the position of these may become less predictable with surgical intervention, particularly if the corpora have been rotated. The other limitation may the position and length of the urethral; this is discussed in the later section. These factors are best assessed with an artificial erection under general anesthesia (GA). Even after reconstruction including corpora corporotomy, the blood flows to each corpus are usually separate. The best way of assessing the corpora involves insertion of large-bore butterfly needles into each side and infusion with pressurized saline (Figures 13.1 and 13.2). This allows regular inflation and deflation throughout if

FIGURE 13.1 Artificial erection being performed on a patient with bladder exstrophy and a marked dorsal chordee.

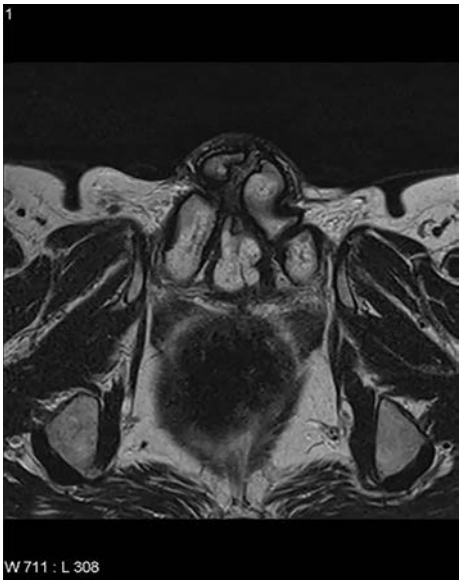

FIGURE 13.2 MRI that demonstrates the distraction of the two corpora with the urethra passing between them.

necessary and avoids the need for a tourniquet, which may mask a very proximal defect or curvature. The patient should be woken after the artificial erection and counseled about the risks and benefits of surgery.

3. The surgical approach with a dorsal chordee may vary depending on the findings of the artificial erection. In principle, the penis will need to be degloved—this is performed after completing an artificial erection to identify the problem. Although a circumferential incision is made, this often needs to be coupled with a longitudinal incision. The location of this is a matter of judgment and may be either ventral or dorsal. This then allows effective degloving of the penis—with dissection of scar tissue. Care needs to be taken in identifying the location of the urethra and the neurovascular bundles. Once the neurovascular bundles have been isolated with a vessel loop, a further artificial erection will identify the precise location of the difficulty and correction can be undertaken. The patient needs to be warned about erectile dysfunction, loss of sensation, skin loss, and penile shortening
4. The urethra in exstrophy is in the epispadic position, and part of the initial reconstruction will have been to try and normalize its position. In assessing a dorsal chordee, it is important to know where the urethral is in relation to the scar tissue between the base of the penis and the anterior abdominal wall. It may be very superficial. If this is the case, then it will be taking a straight-line course to its point of termination. If the penis is straightened, this will increase the distance that the urethra must reach in order to maintain a terminal meatus, as the objective of the operation is to increase the distance between the tip of the penis and the abdominal wall by releasing the chordee. In this situation, the function of the urethra is important. In this young man's case, it is functioning as a seminal conduit. And the creation of a neourethra with buccal mucosa (for example) would almost certainly stenose and fail; therefore, the patient may have to accept a hypospadic meatus as the price of a more functional erection. If the urethra is used for urination, then urethral reconstruction may be achievable to terminalize the meatus.
5. It is reasonably common for these young men with exstrophy and/or epispadias to suffer epididymitis in adolescence. It can be very difficult to treat, as the pathology almost certainly occurs as a result of unavoidable intervention at the bladder neck as part of earlier reconstruction. Conventional antibiotics may be enough to resolve the problem, but if not, testicular damage may result and, in some instances, a vasectomy on the affected side only may be the best way to avoid further testicular damage and preserve fertility.[1–4]

CASE 2: XY DSD

You are asked to see a 16-year-old female patient. You are told that she has a karyotype of 46 XY and has been diagnosed as having complete androgen insensitivity syndrome (CAIS). She has an absent vagina, and you are being asked for help in reconstructing her vagina by your gynecology colleague. She does not have urological symptoms.

Questions

1. What is the current classification of disorders of sex development (DSDs)?
2. What is the classical presentation of a patient with CAIS? What would you expect to see as external and internal genitalia?
3. How would you advise her regarding her gonads? What is the risk of malignancy?
4. What are her options for vaginal reconstruction?

Discussion

This is a complicated subject and worth reading about. There are some excellent texts, and this short summary is not a replacement for them. The elements of sex development are chromosomal, gonadal, and hormonal. Any of these may take an abnormal course in either isolation or combination. Remember that the default for sex development is female, and that a fetus has to have particular factors (chromosomal, gonadal, and hormonal) in place to make it male. In examining a patient, try to think about whether he or she is an overvirilized female or an undervirilized male. Table 13.1 shows the current (2012) accepted nomenclature.

TABLE 13.1 Current classification of DSD

Classification	Examples
46 XX DSD	Congenital adrenal hyperplasia (by far the most common)
46 XY DSD	Androgen insensitivity syndromes, 5-alpha-reductase deficiency, abnormal MIS activity; there are other examples
Gonadal dysgenesis	A failure in gonadal development with a spectrum of presentations
Ovotesticular DSD	Both ovarian and testicular tissue present (previously called true hermaphroditism)

FIGURE 13.3 Gonadectomy being performed on a patient with XY female DSD (CAIS).

1. If the androgen blockade is truly complete, this young patient will be born with a phenotypically female appearance. If there is a partial blockade, there may be some androgenous features, such as clitoromegaly. In complete androgen insensitivity, it would be very possible to raise this baby as a girl with no knowledge of any concerns. Close inspection of the genitalia may reveal the lack of a vagina or a small pit—this may be very difficult to spot. There is usually no evidence of female internal genitalia; these do not develop because of testicular excretion of Müllerian inhibiting substance (MIS). Under these circumstances, this girl is likely to present with primary amenorrhea.
2. The gonads are most commonly intra-abdominal testes—they may be felt in the groin in some. In infancy, the concern relating to gonads is that any sensitivity to androgens (i.e., a partial insensitivity syndrome) would result in androgenization when she reaches puberty, i.e., clitoral growth and male pattern physical development and hair growth. On these grounds, some would argue for early removal (see Figure 13.3). Increasingly, patient groups are suggesting that they have a better puberty and a greater sense of well-being with the background production of testosterone. In fact, some female XY DSD patients are deliberately retaining their gonads. The malignant risk has always been thought of as low, but there are no data under these circumstances and follow-up arrangements for the gonads are very difficult to plan. The other important aspect to this is that retention of the gonads may lead to the ability to harvest spermatozoa and potentially achieve fertility via surrogacy.
3. This girl is unlikely to need any surgery in childhood and may not even be aware of her diagnosis until puberty and amenorrhea trigger investigation. In order to create a functional vagina, she may be able to dilate if there is a pit. In the absence of scar tissue, this would be an excellent option for her. This can be achieved using handheld dilators or the laparoscopic implantation of a Vechietti device (see Figure 13.4). Further reconstructive options exist with the use of perineal skin, peritoneum, or bowel substitution. This is a decision that needs to be made on an individual patient basis, and care should be provided by a multidisciplinary team. The surgery can be complex, but it is very important to account for the shock that disclosure of the diagnosis may create, and it is imperative that the multidisciplinary team includes psychology, gynecology, endocrinology, genetic, and urological support.[4–6]

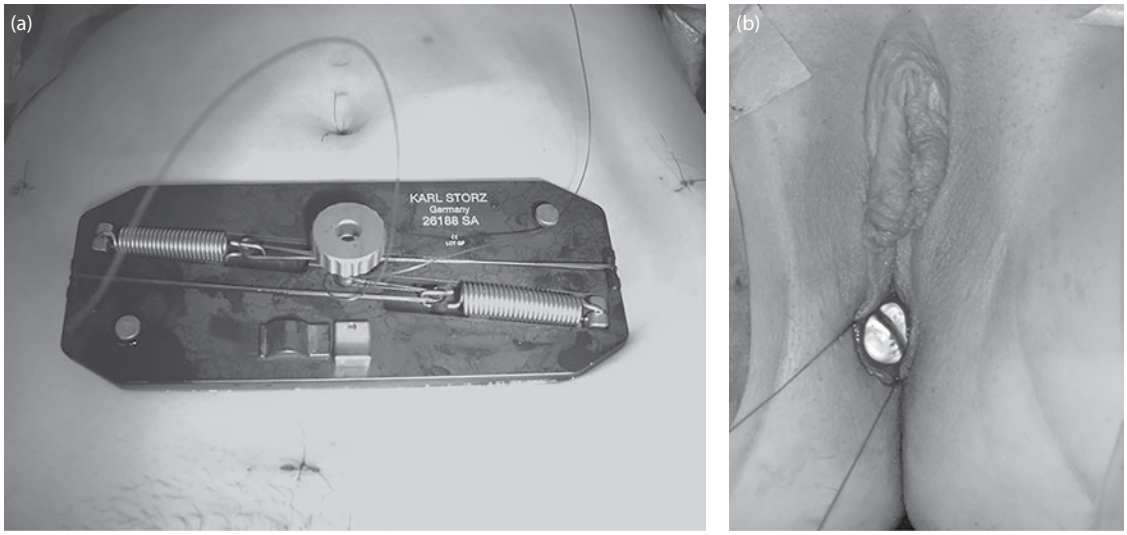

FIGURE 13.4 Device used for a Vechietti vaginoplasty. (a) The device sits on the anterior abdominal wall with tensioning sutures passing laparoscopically to the dilator. (b) The tensioning sutures sit in the vaginal dimple and can be tensioned to create a vaginal tract.

CASE 3: WORSENING RENAL FUNCTION

An 18-year-old gentleman is transferred to your care. He was born with posterior urethral valves. His clinical course has been relatively straightforward through childhood. His last glomerular filtration rate (GFR) was performed 5 years before you see him and was measured as 106 mL/min/1.73 m^2. He is well, but you identify that he has an 800 mL capacity with a 400 mL postvoid residual, and his latest GFR comes back as being 60 mL/min/1.73 m^2.

Questions

1. How would you approach this gentleman's further evaluation?
2. What options do you have regarding his bladder management?
3. Which noninvasive tests should you perform at each clinic visit?
4. Describe how you would obtain pre-operative consent from a patient in order to operate and give the patient a continent catheterisable stoma.

Discussion

1. He needs video urodynamics to understand his bladder function. If there is doubt about upper tract drainage, a MAG3 renogram could be used. Other tests should include evaluation of proteinuria with a protein–creatinine ratio and a serum creatinine. A cystoscopy will rule out a ureteric stricture as a cause of difficulty emptying and ensure visual assessment of the bladder neck.
2. His bladder should be drained completely to avoid urinary tract infections (UTIs) and further renal deterioration. A trial of alpha-blockers may improve emptying if he has a hypertrophic bladder neck. Urethral self-catheterization may be possible, but these boys are normally sensate and therefore find this very uncomfortable. However, it is an important intervention to try, as it does not have any irreversible sequelae. Pediatric series have reported bladder neck incision to improve drainage. The concerns around this relate to induced retrograde ejaculation and the potential impact on fertility (this may already be impaired due to intrinsic semen parameters in valve patients). In considering this, a baseline semen analysis needs to be performed, and if sperm are present, banking should be offered. If the bladder remains a likely culprit and all other avenues fail, a continent catheterizable channel may be the only alternative.
3. It is our practice to perform a urine dipstick to look for proteinuria and to take the blood pressure at each visit. This allows us to highlight concerns earlier and involve nephrological support earlier, when required. Renal preservation with angiotensin-converting enzyme (ACE) inhibitors or receptor antagonists may be used to slow further renal deterioration.
4. The procedure could be performed through either a midline or a Pfannensteil incision. The appendix is used when present and possible (10%–15% are not usable); if not, we make a Monti channel from the small bowel.

FIGURE 13.5 Patient catheterizing his umbilical Mitrofanoff channel.

This is anastomosed to the native bladder to create a flap valve effect. In a good-volume safe bladder, there is no need for an additional cystoplasty. The channel is made using a size 14 Ch catheter, and this is left in place and the channel activated at 6 weeks (practice varies on this time span from 3 to 6 weeks) (see Figure 13.5). Risks include channel failure, leakage, and stenosis (revision between 30% and 50% in the literature, with the highest rate at the skin level). Small bowel obstruction and fistula should be mentioned. The site should be agreed; the umbilicus and right iliac fossa are the two most common. All patients undergoing a new Mitrofanoff procedure will spend about 90 minutes with our specialist nursing team with a video and other counseling to help them understand the procedure. This appears to be time well invested, as those most unhappy with the procedure complain most about a lack of preoperative information or struggling for postoperative support.[7–9]

CASE 4: BLADDER STONES: CYSTOPLASTY MANAGEMENT

You see a 25-year-old male with ambulant spina bifida in your clinic. He had been lost to follow-up for several years. He has returned because he has developed a suprapubic fistula with clear fluid draining out from it. You discover that he has had a cystoplasty and a bladder neck reconstruction in childhood and has recently had an increase in the number of UTIs he suffers with. Computed tomography (CT) of the kidney, ureter, and bladder (KUB) shows 2 large stones in his bladder (see Figure 13.6).

Questions

1. What are the long-term complications of having bowel in the urinary tract?
2. What factors do you know of that increase the risk of stones in a cystoplasty?
3. How would you remove these stones?

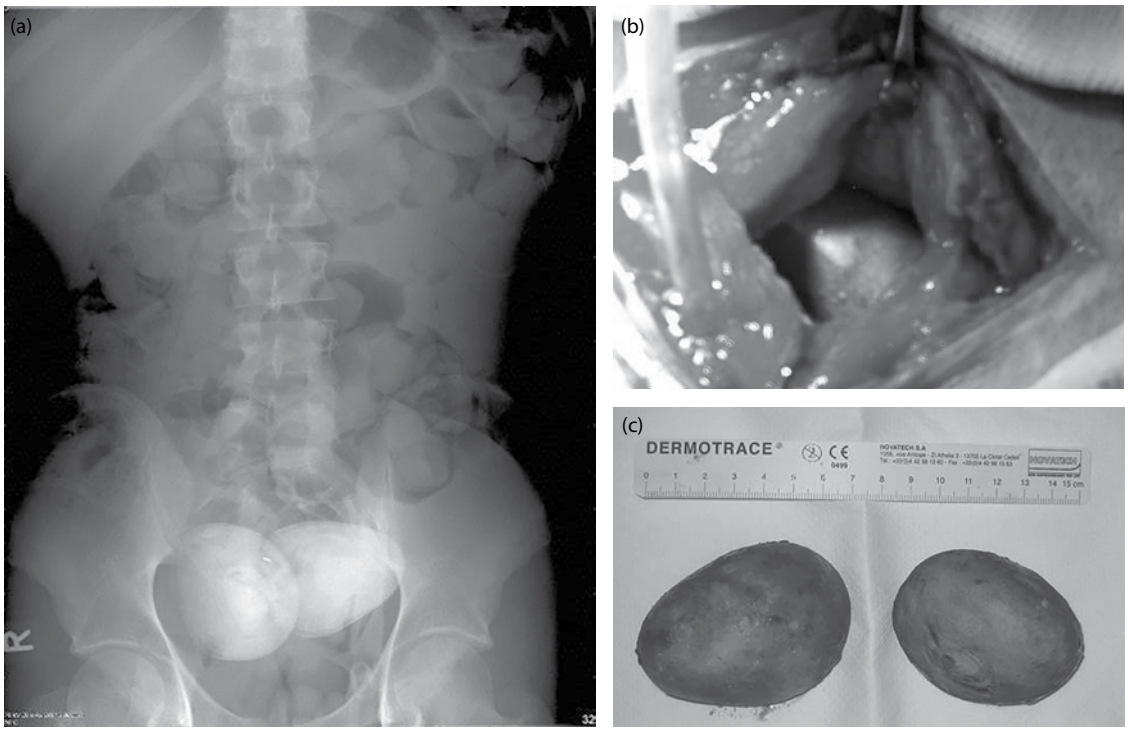

FIGURE 13.6 X-ray (a), open removal (b), and removed bladder stones (c) from a patient with a cystoplasty.

4. What protocol would you use for regular follow-up of patients who have had cystoplasty?
5. What are the arguments for and against routine regular cystoscopy of a patient who has had a cystoplasty?

Discussion

1. The most common complications are mucus production and biochemical changes. When bowel is grafted into the urinary tract, it still continues to behave as a bowel—including its tendency to produce mucus. There has not been any treatment that appears to improve this. Some factors, like infection, diet, or pregnancy, may worsen production. A good fluid intake and bladder washouts are an important part of preventing a buildup. Catheter size is also important. A size 14 Ch catheter is ideal, as it will predictably allow mucus to drain; a size 10 Ch is too small and will not. Many people will manage with a size 12 Ch. Metabolic changes are often subclinical, but a net loss of bicarbonate in exchange for chloride and a tendency to absorb ammonium ions will create hypochloremic metabolic acidosis. If the levels are measured as normal or near normal, treatment is unlikely to be needed, but abnormal levels or symptoms require oral replacement with bicarbonate. Other complications include bowel complications (change in bowel function, small bowel obstruction, and fistulae), UTIs (20%–30%), stones (see Figure 13.6), B12 deficiency (depending on segment used), perforation, and the potential for malignant change.
2. The first and most obvious risk for stone is having had a previous stone, and any patient we encounter that has suffered stones in his or her cystoplasty should be given advice about how to reduce the risk of future occurrences. In a paper that examined the characteristics of those patients who did develop stones, the two most significant findings were the low 24-hour volume in stone formers and lower urinary citrate. An increase in fluid intake ($\geq$2.5 L/day), avoiding salty and high-oxalate food (e.g., rhubarb, spinach, chocolate, and peanut butter), and a healthy balanced diet are important preventative steps. Ensuring regular bladder drainage is vital, and weekly bladder washouts are necessary to ensure there is no mucus buildup. Regular imaging follow-up is also essential in order to detect stones early and remove them before they increase in size.
3. The only option for removing these stones is with an open procedure. The patient has had multiple abdominal procedures and his Mitrofanoff channel is catheterized to allow filling of the bladder. An incision between 5 and 10 cm is made (often using an old scar, size dependent on the size of the stone), the bladder is opened between stay sutures, and the stone is lifted out intact. The bladder is closed in two layers and left on free drainage for 10 days.
4. In our institution, once patients are using their cystoplasty and have passed a trial of void or emptying, they are seen at 6 months with an ultrasound, MAG3 renogram, and blood test (including renal function, bicarbonate, chloride, vitamin B12, and full blood count). The blood test and ultrasound are repeated annually, and a GFR is performed every 5 years. Some would argue that a B12 assay is unnecessary if you know which bowel segment has been taken. We have many patients who have had previous surgery and for whom it is difficult to know which segment has been used. Therefore, since a B12 test is cheap and safe, we

perform this routinely as part of our protocol, as the consequences of missing a deficiency are irreversible neurological deficit.

5. Unfortunately, when cancer has been found in cystoplasties, it has been aggressive in nature, and rarely any have been found with annual screening cystoscopy. They are uniformly discovered during screening intervals on the basis of a symptomatic presentation. Therefore, there is very little argument for annual screening, but a much stronger case for clinical follow-up with aggressive investigation of changed symptoms (e.g., pain, hematuria, or new and recurrent UTI pattern).[6,7,10]

CHAPTER 14

Embryology of the Genitourinary Tract

Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

An understanding of the significant events in the embryology of the genitourinary tract is essential to both the diagnosis of congenital anomalies and the interpretation of pathologic findings that result from disordered embryogenesis. We separate the embryology into several small chapters, each relating to sections of the text organized by system. This short chapter serves as a general introduction to the embryology of the genitourinary tract. Embryologic data are synthesized largely from standard textbooks of embryology,[1–4] but are amplified with newer concepts as they seem clinically pertinent. Particular emphasis is paid to genetic and molecular pathways important in genitourinary tract development. The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Strategic Plan for Pediatric Urology highlights the importance of understanding the cellular and molecular basis of genitourinary tract development to advance the diagnosis and treatment of these diseases.[5] The material is arranged chronologically as well as by organ (system) to provide a better understanding of the interrelationships between structures. A developmental "timeline" is presented at the conclusion of this chapter for easy reference (see Figure 14.1 later in this chapter).

The first events in embryology occur at the time of conception, or fertilization of the ovum by a spermatozoon. It is at this moment, or in the first few subsequent cell divisions, that the chromosomal constitution (karyotype) is established. *The normal human cell contains 46 chromosomes (usually written 46,XY or 46,XX), 23 of which are provided by the maternal gamete (ovum) and 23 by the paternal gamete (sperm). The future individual's genotypic sex is now established as an X chromosome, is provided by the ovum and either an X or a Y chromosome by the sperm.* The presence and expression of the SRY gene, the testis-determining factor located on the Y chromosome, but rarely translocated to one of the other chromosomes, results in maleness.[1,6,7] In the absence of this locus, femaleness is likely to develop. Other non-Y-linked genes involved in sex determination have been found by genetic analysis of XY sex-reversed patients whose phenotype could not be explained by mutations in the TDF gene.[7] In the presence of SRY, the bipotential gonad progresses toward testis organogenesis.[6] SRY expression in Sertoli cell precursors activates downstream effectors, such as SOX9 (SRY-related HMG-box 9), which directs Sertoli cell proliferation and organization.[6] Much less information is known regarding the genes involved in ovarian organogenesis.

It is presumably at conception, as well, that certain other genitourinary abnormalities related to the individual's karyotypic constitution are determined. For example, many of the disorders of sexual development (DSDs) are determined at this time, either as deletions of chromosomes (e.g., Turner syndrome, 45,XO)[8] or as extra chromosomes (e.g., Klinefelter syndrome, 47,XXY).[9] The genital abnormalities of the Aarskog–Scott syndrome are also determined at this moment, as they are carried as an X-linked recessive trait.[10] Many of the trisomy syndromes include abnormalities of the genitalia and of the urinary tract as part of their spectra of expression.[11] The syndrome of Wilms' tumor and aniridia is related to a chromosomal abnormality (deletion of the short arm of the 11th chromosome).[12] Many other urinary abnormalities are probably also determined at this time, although the exact nature of many of these processes is as yet unknown. Others that seem to be familial in nature include duplication anomalies,[13,14] vesicoureteral reflux (VUR),[15,16] congenital ureteropelvic junction (UPJ) obstruction,[17] renal agenesis and dysplasia,[18] and hypospadias.[19] Some have been grouping seemingly different abnormalities in a kindred into one classification—congenital abnormalities of the kidney and urinary tract (CAKUT)—and feel that they are genetically and causally related. Some abnormalities are inherited as autosomal dominant traits (e.g., autosomal dominant [adult] polycystic disease), while others (e.g., autosomal recessive [infantile] polycystic disease and adrenogenital syndrome) are autosomal recessive traits.

Early embryonic life can be negatively influenced by teratogens such as heat, viruses, and drugs (Table 14.1). Maternal hyperthermia can induce neural tube defects in the embryo. Hyperthermic states have also been associated with hypothalamic lesions, leading to micropenis.[11] Some viruses, when they infect the mother, may produce congenital abnormalities in the fetus. Urologic abnormalities appear more frequently than normal in the congenital rubella syndrome.[20] It is well known that maternal ingestion of drugs can affect the developing fetus. Progestational agents may masculinize a female fetus.[21] The maternal production of androgens by ovarian tumors can also masculinize a female fetus. Maternal use of oral contraceptive pills has been theorized to be associated with the development of hypospadias.[22] Use of angiotensin-converting enzyme (ACE) during pregnancy has been associated with renal dysplasia, probably due to the drug's deleterious effects on the developing renal vasculature.[23] The fetal alcohol syndrome, on occasion, includes urinary abnormalities.[24] In addition, the use of anticonvulsant medications during pregnancy has been associated with genitourinary abnormalities in the fetal

TABLE 14.1 Genitourinary tract teratogens

Teratogen	Potential Genitourinary Defect
Maternal hyperthermia	Micropenis
Rubella virus (congenital rubella)	Hypospadias, cryptorchidism
Progestational agents	Ambiguous genitalia
Oral contraceptives	Hypospadias
ACE inhibitors	Renal dysplasia
Ethanol (fetal alcohol syndrome)	Hypospadias, hydronephrosis
Anticonvulsants	Hypospadias, ambiguous genitalia, cryptorchidism
Cocaine	Eagle–Barrett syndrome, hypospadias, hydronephrosis

hydantoin syndrome[25] and the fetal trimethadione syndrome.[26] Maternal use of recreational drugs, such as cocaine and methamphetamine, has been associated with anomalies of the genitourinary system, including Eagle–Barrett syndrome and hypospadias.[27] Excessive vitamin A ingestion during the first trimester of pregnancy has been reported to increase the risk for the development of genitourinary abnormalities.[28] In addition, physical forces (e.g., compression of the fetus within the uterus secondary to oligohydramnios) can induce permanent physical changes in the fetus, even at a relatively late stage of development. These are termed "deformation syndromes," of which Potter's syndrome is thought to be one.[29]

Increasingly, disorders of embryogenesis can be detected on prenatal ultrasound. For this reason, the evaluation of pediatric urological patients often begins in the fetal stage. Urologists are often consulted before the child is born to counsel parents on the prognosis and treatment of the abnormality that has been detected. Moreover, potential parents sometimes seek preconception guidance from specialists regarding genetic risks to a potential fetus. These families are interested in ways to detect and/or quantify these risks and to understand ways to minimize them. Answers to many of these questions are forthcoming as results of detailed molecular and genetic studies continue to provide clinical information.

Recent work on the Sonic hedgehog (SHH) signaling pathway represents an exciting new molecular mechanism important in genitourinary tract development. The hedgehog (HH) gene was initially implicated in controlling segment polarity in fruit fly embryos.[30] SHH, the best-studied homologue of HH, has recently been shown to play a functional role in genitourinary tract morphogenesis and differentiation.[30,31] As we continue to expand our understanding of these cellular and molecular mechanisms involved in genitourinary tract development, clinical applications and improvement in genetic counseling will surely follow.

CHAPTER 15

Adrenal or Suprarenal Gland Development

Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

The developing fetal adrenal gland plays an essential role in intrauterine homeostasis, fetal organ maturation, preparation for extrauterine life, and parturition.[1]

The adrenal or suprarenal glands are located near the superior poles of the normally placed kidneys and contain two distinct different functioning areas of tissue, the cortex and the medulla. Although anatomically very close, the cortex and the medulla arise from two different and distinct areas. *The adrenal medulla is derived from migrating ectodermal neural crest cells. The cortex develops from the primitive mesoderm medial to the urogenital ridge, starting about the fourth gestational week.* By the sixth week, the cortex is apparent as an aggregation of mesenchyme on either side of the root of the mesentery and the developing gonad. At this time, nerve fibers, which the developing medullary cells will traverse, penetrate the developing adrenal cortex. The cortex develops two distinct areas by the eighth gestational week. The central area or the fetal zone is laterally and centrally located, while a thin rind develops on the outer aspect of the adrenal as the ultimate definitive adult cortex. The fetal zone comprises about 85% of the developing fetal adrenal gland.[2] The definitive cortex begins to differentiate into hormone-producing zones, the zona glomerulosa and the zona fasciculata, late in gestation. Most of the developing proliferation during the latter part of gestation is in the peripheral cortex region. The zona reticularis does not become apparent until about the end of the third year of life (Figure 15.1). The zona glomerulosa or outermost layer of the definitive cortex produces aldosterone. The zona fasciculata and zona reticularis form a unit after the reticularis develops in early childhood. The zona fasciculata produces the glucocorticoid hormones, while the zona reticularis produces the sex or androgen hormones.

Adrenal arterial circulation develops from developing descending aorta; several arteries feed the adrenal cortex and infiltrate from the cortex to the medulla in a fine network of vessels. A central vein drains each adrenal gland. Angiogenesis, the formation of new capillaries from preexisting blood vessels, is essential for the rapid growth of the fetal adrenal typically occurring in midgestation. Because of the required delivery of steroid precursors during development, the fetal adrenal requires extensive vasculature. Ishimoto et al. found through immunostaining of pathologically obtained fetal adrenal glands that the primary site of angiogenesis is in the periphery of the developing gland. They found that angiogenic factors (Ang2, VEGF-A, and FGF-A) were locally produced and induced fetal adrenal angiogenesis. Proliferation of the vascular endothelial cells appears to be limited to the periphery of the definitive zone during midgestation.[1]

The adrenal glands increase in size from around the second to third month of gestation, growing from about 5 to 80 mg, and are much larger than the adjacent kidney for much of development and remain large even after birth (Figure 15.2). Most of this mass is due to the fetal cortex and the developing definitive adult cortex; the adrenal medulla is quite small until after birth. The adrenals lose most of their mass shortly after birth, with about one-third of the weight lost in the first 2–3 weeks after birth (Figure 15.3). The loss in mass is due to the involution of the large fetal cortex zone. The original weight is not regained until about the end of the second year of life.

The adrenal cortex arises from the common adrenogonadal precursors in the intermediate mesoderm. The rudimentary adrenal gland fetal zone expresses 17-α-hydroxylase (CYP17), which is a steroidogenic enzyme. During development, the fetal zone expresses cholesterol side-chain cleavage exzyme (CYP11A) and CYP17, which drive the fetal adrenal to produce primarily dehydroepiandrosterone (DHEA) and its derivatives. Ultimately, the adrenal cortex encapsulates when the neural crest cells migrate to form the adrenal medulla.[3] Some primitive adrenocortical cells may migrate beyond the normal suprarenal location during formation. Accessory adrenocortical rests may be found adjacent to the celiac plexis, in the broad ligament, near the ovarian or spermatic vessels or around the kidneys or uterus. Rarely, these rests may be found near other abdominal organs or even the lungs or spinal nerves, or in the brain. Some of these rests may be responsible for Cushing's disease or malignant degeneration.[4]

The medulla arises from the neural crest cells of the primitive sympathetic nervous system. The migrating neuroectodermal cells differentiate into neuroblasts, ultimately forming the paravertebral and para-aortic sympathetic ganglia, and pheochromoblasts, which form catecholamine-secreting chromaffin cells. The chromaffin cells are found throughout the adrenal medulla and the sympathetic chain in the fetus, but the extra-adrenal sites generally involute after birth. Persistent extra-adrenal tissue can be found near the origins of the celiac and mesentery arteries; another site, the organs of Zuckerkandl, is located near the inferior mesenteric artery and may be prominent during the first year of life, after which this

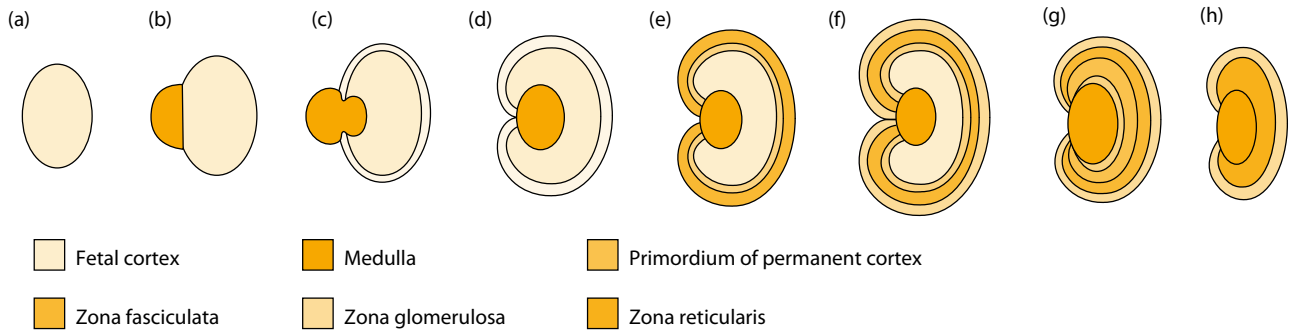

FIGURE 15.1 Schematic drawings of the development of the suprarenal gland. (Adapted from Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*, 7th edn. Philadelphia: Saunders, 2003.)

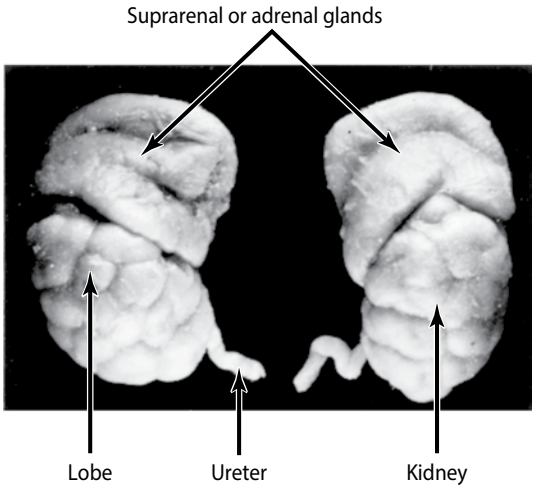

FIGURE 15.2 Photograph of kidneys and adrenal glands of a 28-week fetus. (Adapted from Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*, 7th edn. Philadelphia: Saunders, 2003.)

tissue generally involutes but may be a site of extra-adrenal pheochromocytoma development later in life.

The fetal adrenal cortex produces large amounts of dehydroepiandrostenedione sulfate (DHEA-S) after the first trimester. Induction of DHEA and DHEA sulfate occurs when the fetal zone expresses the 450C17 enzyme. Steroidogenesis is regulated by steroidogenic factor-1 (SF-1) and dosage-sensitive sex reversal-adrenal hypoplasia congenita (DAX-1) found on a critical region on the X chromosome gene 1. DAX-1 is a negative regulator of SF-1, which is an activator of steroid hormone production.[2] Steroidogenesis during the second trimester occurs in the fetal zone, while it is absent in the definitive zone at the same time period. DAX-1 is found during the second trimester in both the nucleus and the cytoplasm in the inner and outer fetal gland, as it is found on immunochemical staining of pathologically obtained fetal adrenal glands. Battista et al. found while staining this tissue that the extracellular matrix plays a critical role in modulating cell proliferation, apoptosis, and steroidogenesis. The adrenocorticotropic hormone (ACTH) stimulates the nucleus of the fetal zone cells activating DAX-1-negative modulation of fetal adrenal steroidogenesis. The stimulation activates the highly proliferative definitive zone, whereas the stimulation does not cause fetal zone cells to proliferate.[2] The outer cortex is believed to produce cortisol after about 28 weeks' gestation, although cortisol can be measured as early as the eighth gestational week.

Kim et al. also found that DAX-1 was expressed in the fetal zone initially, but when the definitive zone arises, it is found to be active in the subcapsular zone of the adrenal gland, as it stimulates cell growth through regulation by orphan nuclear receptor (Sf1).[5] They propose that DAX-1 is activated to stimulate cell growth by glucocorticoids released by the differentiated cortical cells, whereas ACTH stimulation inactivates DAX-1 while stimulating steroidogenesis by the adrenal cortical

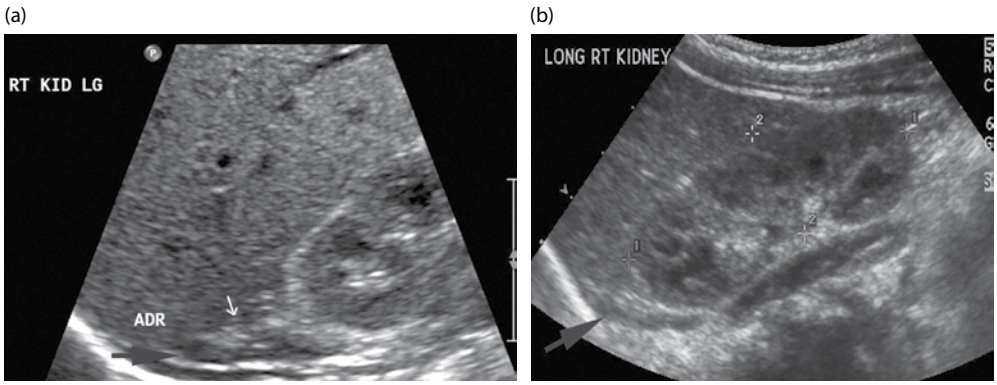

FIGURE 15.3 Ultrasound images of adrenal gland in 2-week-old boy (a) and at 4 months old, demonstrating involution of the gland size after the first month of life (b).

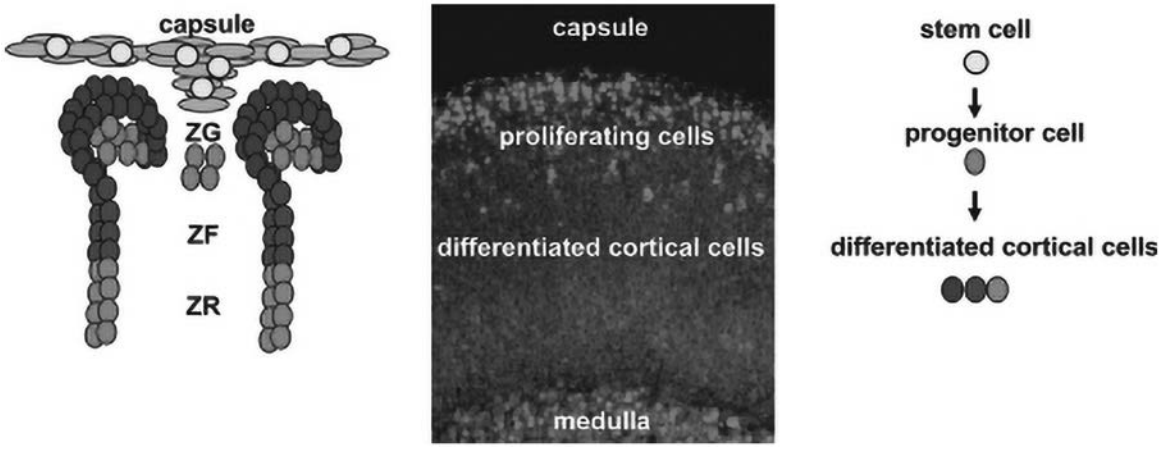

FIGURE 15.4 Cellular organization of the developing adrenal cortex. (Adapted from Kim AC et al. *Endocr Rev* 2009;30(3):241–63.)

cells.[5] The developing adrenal gland also produces large amounts of inhibin-α, specifies adrenal cell development, and prevents development of ovarian-like tissue, as both tissues develop from the same band of adrenogonadal primordia (Figure 15.4).

The definitive zone cells located in the periphery are nonsecretory until the second trimester. These cells proliferate rapidly and move into the outer layers of the fetal zones centripetally, and then differentiate into steroid-producing cells. By the end of the second trimester, a third transitional zone is found between the first two zones.[6,7] Angiotensin II (AngII) is expressed through two subtypes in the fetal adrenal gland: the AT2 subtype is found in the fetal zone, and AT1 is found in the definitive zone after the 16th week of pregnancy. AT2 regulates apoptosis in the fetal zone during adrenal development. The development of the fetal adrenal gland depends on proliferation at the periphery in the definitive zone and apoptosis in the central fetal zone. Chamoux et al. found that primary extracellular matrix in the developing adrenal gland composed of collagen IV increased cell responsiveness to ACTH and AT1 receptor effects of AngII, while laminin reduced cell responses to ACTH and AT2.[6,7] Stimulation of cortisol secretion by ACTH is enhanced in the fetal zone due to large volumes of collagen IV in that area, as well as also being found in the smaller, more compact, definitive zone. They found laminin mostly concentrated in the periphery and the fibronectin mostly located in the central zone. These extracellular matrix proteins enhanced peripheral cells of the developing outer cortex to proliferate while maintaining central fetal zone cells for further steroid secretion from its cells.[6,7]

The fetal hypothalamic–pituitary–adrenal (HPA) axis is an example of reciprocal induction where the development, differentiation, and maturation of vital organ systems (lungs, brain, and liver) for immediate postnatal survival and parturition are hinged on interactions between the organs of the developing endocrine axis.[8] The hypothalamus releases corticotrophin-releasing hormone (CRH) as early as 8–12 weeks' gestation. CRH regulates the growth of the pituitary corticotrophins (adrenocorticotrophin and ACTH proopiomelanocortin [POMC]) and mRNA expression, as well as acting as a potent vasodilator of the fetoplacental circulation, and potentiates local prostaglandin and oxytocin function for uterine contractions during labor.[9] Placental estrogens facilitate conversion of fetal cortisol to inactive cortisone, which causes negative feedback on the fetal HPA axis, resulting in increased POMC mRNA, ACTH, adrenal cortisol, and DHEA-S production. Interestingly, increased fetal adrenal glucocorticoid stimulates the release of placental CRH, which increases the stimulation on the fetal pituitary to increase ACTH release, which then causes the adrenal to produce more cortisol, which is critical for the transition from fetal life to extrauterine life at the end of gestation. The importance of this upregulation of cortical hormone for transition to infant well-being and survival after delivery has been shown in outcome studies of extremely preterm small

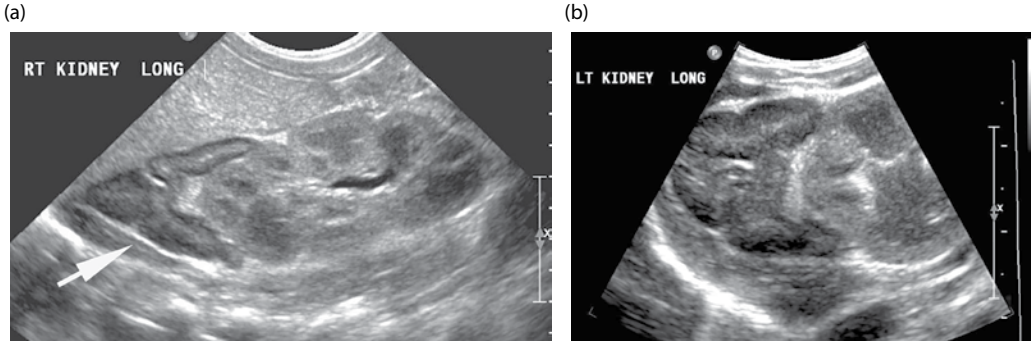

FIGURE 15.5 Adrenal glands in infant girl with CAH (sizes at this age are similar to those of newborns not affected by CAH).

neonates who were delivered prior to attaining the normal adrenal developmental milestones in utero.[9,10]

A serious and potentially life-threatening condition is congenital adrenal hyperplasia (CAH), which is a group of autosomal recessive disorders, the most common of which is caused by a mutation of the cytochrome P450 21-hydroxylase (CYP21) gene. This mutation causes deficient production of the cortical enzymes necessary for producing corticosteroids or mineralosteroids needed for life. Other forms of CAH are not as common, and the etiology of the defects is also not as well known. The decreased cortical hormone production stimulates the fetal pituitary to produce more ACTH, which then causes the adrenal to enlarge and produce more adrenal androgens and androgen precursors that do not require 21-hydroxylation. The excess androgen activity will cause masculinization of female fetuses. The excessive hormone production must occur within the first trimester to produce the masculinization changes that can only take place during early genital development (Figure 15.5).[11,12]

It is believed that adrenocortical carcinomas that develop later in life are mostly monoclonal in origin. Certain hereditary adrenocortical carcinoma syndromes, such as Beckwith–Wiedemann syndrome (BWS), familial adenomatous polyposis (FAP), and Li–Fraumeni syndrome, are thought to arise because of problems with regulation of cell development and apoptosis. It has been found in BWS and FAP that the genes IGF-II and IGF-I are critical for normal progenitor development.[5]

During the pregnancy, especially during the second and third trimesters, levels of DHEA and DHEA-S are very high, as are the levels of 3β-hydroxysteroid dehydrogenase. At birth, the fetal adrenals undergo massive involution, losing about 50% of their mass in the first month of life. Rapid decline in androgen secretion follows the decreasing postnatal size of the adrenal gland. Ben-David and colleagues found that DHEA-S, cortisol, and androstenedione levels decrease with birth, as does the rapid postnatal involution of the fetal adrenal gland, regardless of gestational age.[13] This involution, which is not dependent on fetal age at birth, implies that parturition itself is responsible for fetal adrenal involution and maintenance of a normal functioning adrenal gland for the neonate after birth. Fetal adrenal production of androgens depends on 17-hydroxylase activity. Parturition with accompanied involution of the fetal adrenal shows a marked drop in 17-hydroxylase activity. Any rise in androgen production in boys is due to gonadal activity after birth.[13]

CHAPTER 16

Radiological Assessment of the Adrenal

Kourosh Afshar, Douglas H. Jamieson, and Andrew E. MacNeily

INTRODUCTION

Diagnostic imaging is an essential part of the investigation of adrenal disorders. Modalities such as ultrasound, MRI, and computed tomography (CT) scan have replaced older techniques, such as intravenous urography and angiography. In this chapter, we discuss the imaging characteristics of the more common childhood adrenal abnormalities (Table 16.1).

SOLID MASSES OF THE ADRENAL

Neuroblastoma

If a solid adrenal mass is encountered when a child is imaged, neuroblastoma must always be considered. These are malignant tumors originating from neural crest cells with a peak age incidence of 2.5 years. They arise from the adrenal medulla in 40% of cases, the remainder being extra-adrenal in origin. Although they can be detected incidentally at the time of imaging for other indications, neuroblastoma usually presents as a large abdominal mass and is metastatic in 70% of cases at the time of presentation.[1]

Calcification, which is amorphous and speckled, is seen on up to 50% of plain abdominal radiographs and 80% of CT scans.[2] On ultrasound, tumors are solid and heterogeneously echogenic with occasional hypoechoic areas.[3] Ultrasound is a useful method for follow-up.

Cross-sectional imaging (CT or MRI) depicts a large irregular mass and punctuate calcification with or without enlarged lymph nodes or visceral metastases.[4] Neuroblastoma tends to cross the midline and encase vascular structures. It displaces the kidney laterally and inferiorly (Figures 16.1 and 16.2). These features are helpful to differentiate neuroblastoma from a large Wilms' tumor.[5] On CT, areas of low attenuation often represent cystic necrosis or hemorrhage (Figures 16.3 and 16.4a,b).[5] On MRI, the mass has low or intermediate signal intensity on T1-weighted images and high intensity on T2-weighted images.[6] CT- or MRI-based myelograms are useful in selected cases to assess the extent of intraspinal extension, presenting as a dumbbell-shaped tumor (Figures 16.5a and b and 16.6a–c).[7] Some authors prefer MRI for cross-sectional imaging for better delineation of hepatic metastasis, vascular involvement, and intraspinal extension.[8] Iodine^{132} or I^{131} or I^{123} metaiodobenzylguanidine (MIBG) scintigraphy demonstrates uptake by the primary tumor and any metastatic sites, such as bone.[9,10] However, MIBG has up to 30% false-negative results in diagnosing primary tumors and is less sensitive than 99m technetium methylenediphosphonate (^{99m}Tc MDP) at diagnosing bony metastases. In practice, the 2 tests are used to complement each other.[5,11] A recent study concluded that both CT and MRI have poor accuracy for estimating local extension, but when either modality is combined with ^{99m}Tc MDP scintigraphy, they are equally useful in diagnosing stage 4 disease, with an accuracy of 90%.[12]

TABLE 16.1 Differential diagnosis of antenatally detected adrenal masses

Adrenal hemorrhage
Neuroblastoma
Renal duplication anomaly
Pulmonary sequestration
Enteric duplication

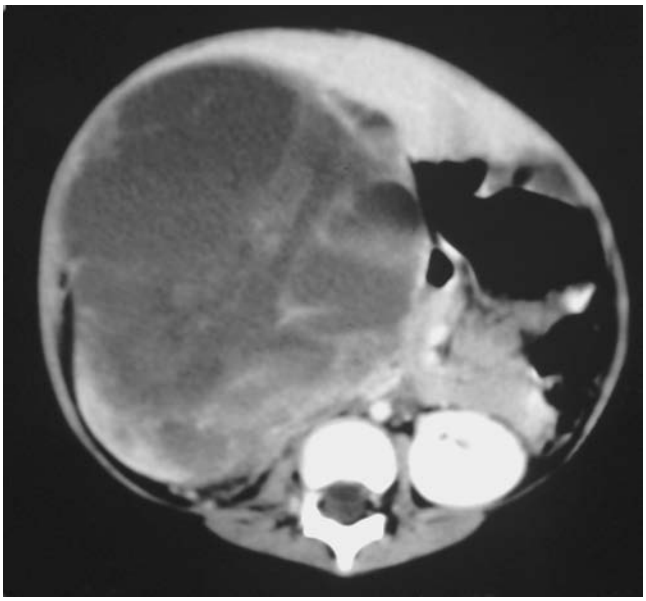

FIGURE 16.1 Contrast-enhanced CT demonstrates a large heterogeneous mass with areas of nonenhancing low density. It is difficult to separate a mass arising from the upper pole of the right kidney from an adrenal mass. The tumor renal interface is indistinct.

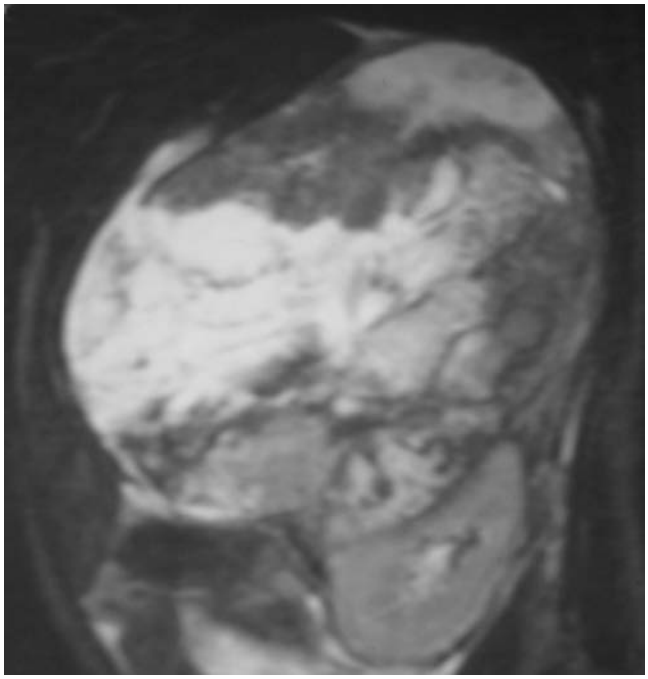

FIGURE 16.2 Sagittal T2-weighted MR image clearly demonstrates a tumor mass displacing the right kidney inferiorly, confirming adrenal mass. The mass has large areas of increased T2 signal intensity corresponding to the low-density areas on CT (Figure 16.1). Areas of tumor necrosis or old areas of hemorrhage are suspected.

FIGURE 16.3 Contrast-enhanced CT in a 4-year-old child presenting ill, with weight loss and a hard abdominal mass. There is a large mass in the left adrenal or retroperitoneal location. Dense areas of opacity indicate calcification. The mass enhances poorly and inhomogeneously. Lymphadenopathy surrounds the aorta, displacing it away from the vertebral body. Histology confirmed neuroblastoma.

Ganglioneuroma and Ganglioneuroblastoma

These benign tumors arise from sympathetic ganglions and represent a more differentiated form of neuroblastoma. On CT, they manifest as an oval, discrete mass

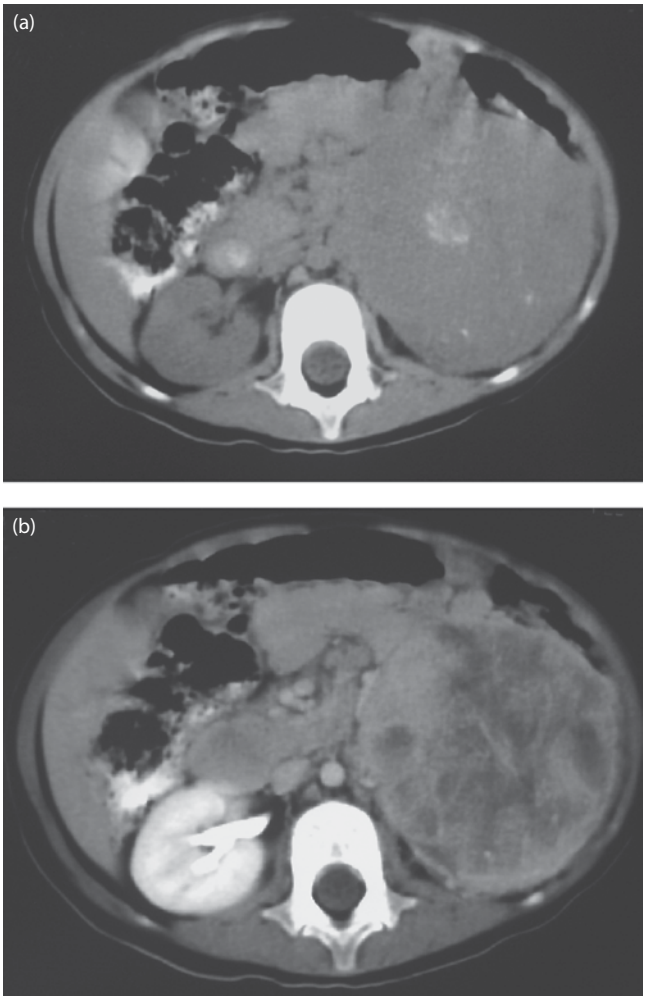

FIGURE 16.4 (a) Nonenhanced CT demonstrates a large left neuroblastoma mass with calcification. Note that the nodal spread to the right renal hilar region also has calcification. (b) Contrast-enhanced CT slightly inferior to (a) shows marked inhomogeneity of enhancement.

with variable enhancement. Calcification that is usually not as extensive as in neuroblastoma is seen in 20% of cases. On MRI, the mass has a low-intensity signal on T1 and a high-intensity one on T2 images, with a characteristic whorled appearance.[13] Ganglioneuroblastoma is an intermediary tumor of sympathetic tissue containing both benign and malignant elements. It has variable imaging features, depending on the composition of the tumor.[13]

Ganglioneuromas are generally more homogeneous with a lower T1 intensity than the liver.[14]

Pheochromocytoma

Also a tumor of neural crest cells, pheochromocytoma tends to occur in older children compared with neuroblastoma. The main presentation is a headache due to hypertension.[15] The only reliable criteria for malignancy are local invasion and metastasis. On ultrasound, the tumor is seen as a hypoechoic mass, occasionally containing small cysts. Generally, CT and MRI are both highly (>90%) sensitive

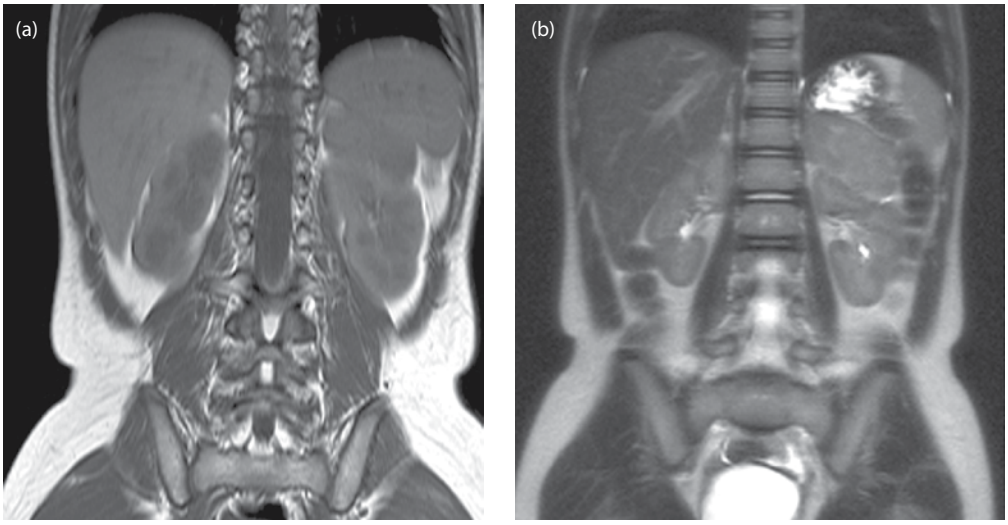

FIGURE 16.5 Coronal T1 MR image (a) and coronal T2 MR image (b) demonstrate a left adrenal mass that is homogenous and has soft tissue signal characteristics. This is usual for a smaller neuroblastoma, where tumor necrosis and hemorrhage are less encountered. Note that MR can easily miss calcification, although this has little impact on diagnosis.

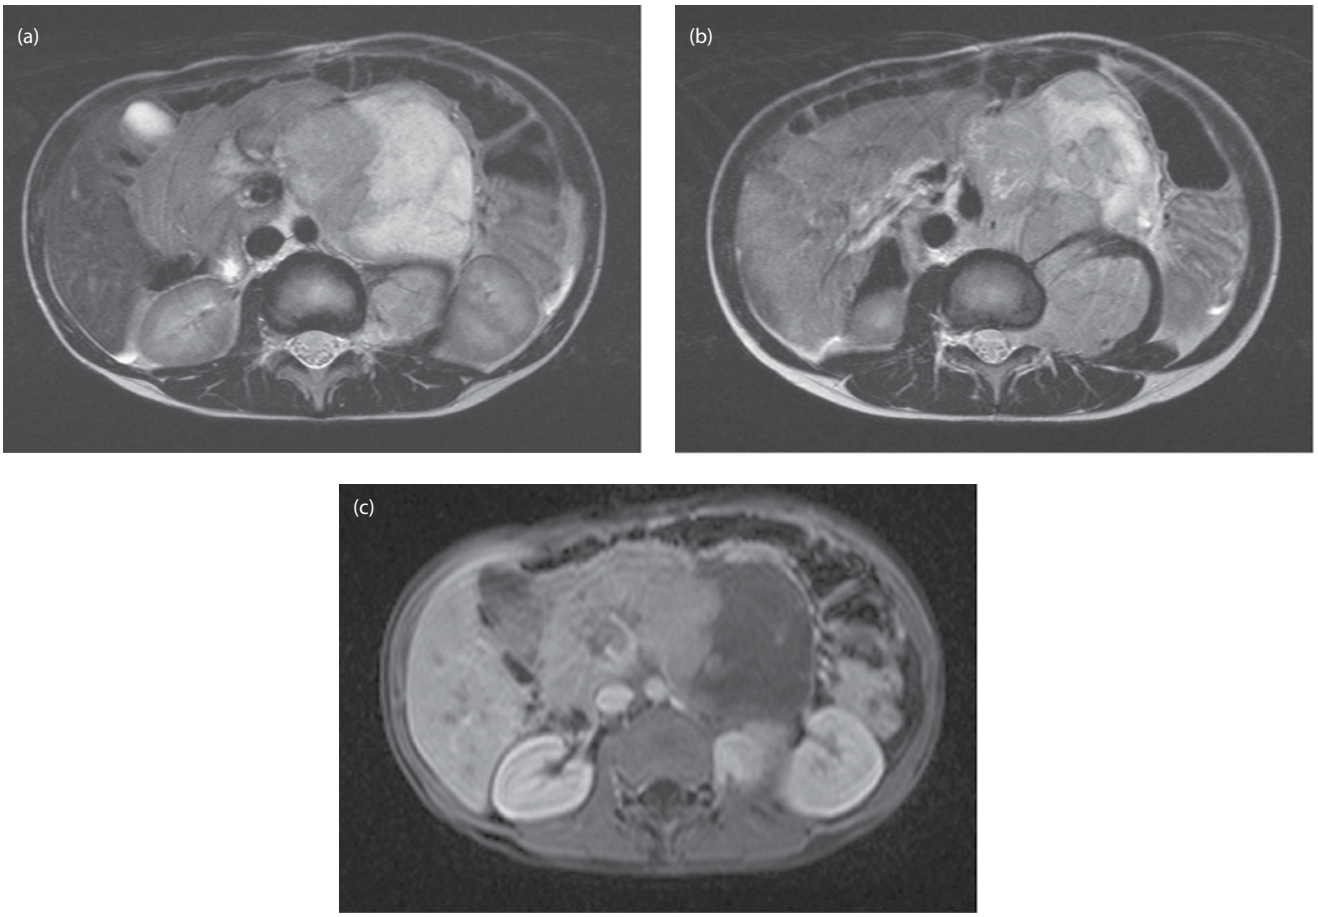

FIGURE 16.6 Axial T2 MR image (a and b) and gadolinium-enhanced fat-saturated T1-weighted MR image (c). Large heterogeneous tumor mass crossing the midline is well delineated. The extensive left-sided area of increased T2 signal intensity shows no contrast enhancement and suggests tumor necrosis. It would be important to direct biopsy away from this area to obtain appropriate diagnostic information. Note also the tumor encroachment on the left-sided neural foramen (b). Evaluation of tumor extent into the spinal canal is superbly imaged by MRI.

and specific in diagnosing and staging pheochromocytomas, but because of the possibility of a hypertensive crisis, induced by the iodinated contrast material, some authors prefer MRI as the first choice for cross-sectional imaging. However, at least one study has demonstrated that nonionic contrast agents are safe in the setting of a confirmed pheochromocytoma.[16] On unenhanced scans, tumors are isodense to the surrounding soft tissue but enhance intensely following IV contrast.[17] MRI generally characterizes these tumors as possessing low signal intensity on T1-weighted images and a characteristic marked increased signal intensity on T2 images secondary to their high vascularity.[18] More recent studies have shown variability in T2 signal, with up to 30% of cases having low signals.[13] MIBG scans have a sensitivity and specificity of 90% in detecting functioning tumors, but without the anatomic resolution provided by cross-sectional imaging.[4,19] MIBG combined with single-photon emission computed tomography (SPECT) is useful in detecting equivocal cases.[20]

Cortical Neoplasms

These are rare tumors of childhood mostly associated with endocrine syndromes.[21] In the absence of metastasis, the distinction between adenoma and carcinoma is very difficult, even with a histological study of the removed tumor.

On ultrasound, these tumors present as round or ovoid masses, commonly lobulated. They may be hypo- or hyperechoic, and the larger tumors are inhomogeneous.[22,23] On CT, they manifest as circumscribed and heterogeneous masses. The criteria used in adults to differentiate between adenoma and carcinoma, such as unenhanced densiometry and size, have not been studied adequately in children. On MRI, cortical neoplasms have intermediate-intensity T1 and high-intensity T2 signals.[24] Chemical shift MRI has been shown to be a reliable modality for differentiating adenomas from malignant lesions in adults.[25]

Myelolipoma

This rare benign tumor is composed of adipose and bone marrow elements. The diagnosis is made based on the demonstration of macroscopic fat on CT or MRI.[26] On CT, areas of macroscopic fat have a low Hounsfield unit (<30). On MRI, fat is characterized by a hyperintense T1 signal that reduces with fat suppression.

Adrenal Metastases

Metastatic lesions presenting as an adrenal mass are rare in children. The likelihood of adrenal metastasis with no history of previous cancer is extremely low.[27]

The imaging criteria to differentiate primary adrenal adenomas from secondary tumors, as described in adults, such as attenuation values of more than 10 Hounsfield units or signal loss of less than 20% in chemical shift MRI,[28] have not been studied in children. Fluorodeoxyglucose positron emission tomography–computed tomography (FDG PET-CT) has been shown to have an accuracy of more than 90% to diagnose adrenal metastases.[29]

Renal Lesions

Lesions in the upper pole of the kidney should be included in the differential diagnosis of an adrenal mass. Wilms' tumor, renal cell carcinoma, and a hydronephrotic upper-pole moiety of a duplicated system can all masquerade as a primary adrenal mass.

CYSTIC MASSES OF THE ADRENAL

These lesions are usually unilateral and asymptomatic. They may be classified as pseudocysts or endothelial, epithelial, or parasitic cysts. Pseudocysts are formed following hemorrhage into normal or abnormal adrenal tissue. Examples include bleeding into or necrosis of a neuroblastoma or adrenal carcinoma. Calcification is common. Endothelial cysts are the most common category in some series.[30] They may have a vascular or lymphatic origin, and are lined by the corresponding endothelium.[31] Epithelial cysts may be true glandular cysts or embryonal or cystic adenoma.[32] Hydatid cysts constitute the majority of parasitic cysts described in the literature.[33] Typically, cysts are hypoechoic on ultrasound. They possess low intensity on T1-weighted MRI and high intensity on T2-weighted MRI. Treatment of adrenal cysts depends on the underlying pathology and ranges from percutaneous aspiration of cysts containing water density fluid, to laparoscopic or open adrenalectomy for more complex lesions.[34]

ANTENATALLY DETECTED ADRENAL MASSES

With the advent of routine maternal fetal ultrasound, the detection of fetal adrenal masses is becoming increasingly common. Most of these lesions are detected in the third trimester, with the majority being cystic or cystic and solid in nature. Ultrasound is the modality of choice for initial and follow-up evaluation of these findings. In neonates, the normally large adrenal glands are clearly visualized and consist of a hypoechoic cortex and a thin echogenic medulla. The differential diagnosis for antenatally detected adrenal masses is shown in Table 16.2. The intensity of imaging and clinical management of these incidental findings must strike a balance between aggressive surgical intervention for a presumed malignancy and watchful waiting for a benign condition, or one that has a natural history of spontaneous involution.

In a retrospective study of 30 prenatally diagnosed adrenal masses reported from Paris, 13 (43%) were ultimately found to be neuroblastoma, with the remainder representing mainly adrenal hemorrhage with the rare pulmonary sequestration.[28] In a more recent series, 13 out of 18 prenatally diagnosed adrenal masses were neuroblastomas, mostly stage 1 (Figure 16.7).[35] Antenatally detected neuroblastoma can be either cystic or solid. Of importance is the fact that MIBG scanning only provided a 70% sensitivity and a 55% negative predictive value for neuroblastoma in this population. Similarly, urinary catecholamines provided only 36% sensitivity and a 72%

TABLE 16.2 Imaging characteristics of pediatric adrenal masses

Adrenal mass	Ultrasound	CT scan	MRI	Nuclear scan
Neuroblastoma	Solid mass, heterogeneous echotexture	Heterogeneous, low attenuation areas of hemorrhage or necrosis, calcification up to 80%	Heterogeneous signal on T1 and high signal on T2	MIBG avid in 70% 99 Tc MDP more accurate for bone metastasis
Ganglioneuroma	Solid oval or lobulated mass	Homogeneous attenuation lower than muscle, varying degree of enhancement	Homogeneous low signal on T1 and whorled appearance on T2 with varying degree of enhancement	MIBG may be positive
Pheochromo-cytoma	Solid tumor, possible cystic area	Intense enhancement with contrast, low attenuation areas of necrosis/hemorrhage	Low intensity T1, extremely high intensity T2 signal	90% MIBG avid
Adrenal cortical neoplasm	Lobulated solid mass	Heterogeneous attenuation	Low T1 and high T2 signal intensity	
Metastasis		Attenuation <10 HU	Signal drop <20% in chemical shift MRI	
Adrenal hemorrhage	Initially hyperechoic with gradual liquefaction	Initial high attenuation (50–60 HU) with no enhancement	Initially: Low signal T1 Intermediate (1–5 weeks): High signal T1 and T2 Late (weeks to months): Low signal T1 and T2	

Abbreviation: HU, hounsfield unit.

negative predictive value. Postnatal features suggestive of neuroblastoma include large size (>3 cm), homogenously solid nature, and growth on serial follow-up. Conversely, development of calcification in follow-up, shrinkage in size, or development of internal echoes suggests a resolving adrenal hemorrhage (Figure 16.8a and b).[36]

Although adrenal hemorrhage classically occurs in the first few days of life in association with neonatal sepsis or other stressors, it may be observed in the second or third trimester of pregnancy, and therefore clinical features alone are inadequate to determine a diagnosis.[37] It is the most common neonatal adrenal mass, and occurs on the right side in 70% of cases. This latter characteristic is thought to be secondary to adrenal compression between the liver and kidney anteriorly and the spine posteriorly.[38]

FIGURE 16.7 Contrast-enhanced CT scan confirmed the antenatal and postnatal detection of a left adrenal cystic lesion. Surgical removal confirmed the diagnosis of a pulmonary sequestration.

Early ultrasound of an adrenal hemorrhage depicts a hyperechoic mass. Over the initial few days, the hematoma gradually liquefies (Figures 16.9 and 16.10). Complete resolution takes up to 6 weeks with occasional calcification or pseudocyst formation.[39] CT and magnetic resonance (MR) scanning are necessary only in selected cases to determine whether blood is the sole component of a mass, a finding that most likely indicates a benign cause. Acutely, CT of an adrenal hemorrhage is manifested as a well or poorly defined mass with increased attenuation (50–60 Hounsfield units) that does not enhance with intravenous contrast (Figure 16.11 and Table 16.2). In the acute phase, MRI of hematomas demonstrates a reduced signal on T1-weighted images. Methemoglobin in the subacute phase (1–5 weeks) causes high signal on both T1- and T2-weighted images. Chronic hemorrhage (5 weeks to 10 months) demonstrates the gradual formation of low signal hemosiderin.[38,39]

For small antenatally detected lesions, an initial postnatal ultrasound, MIBG scan, and urinary catecholamines should be routine. If initial investigations are suggestive of a benign process, then monthly ultrasounds for the first 6 months suffice. Surgical removal is recommended for an increase in size, elevated urinary catecholamines, or failure of involution with observation.[40]

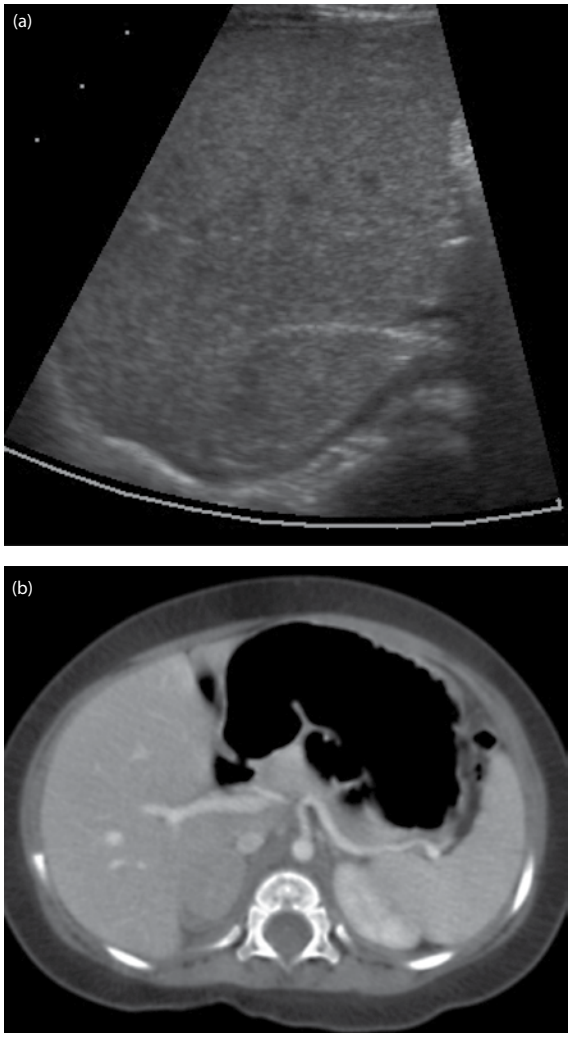

FIGURE 16.8 (a) Neonatal ultrasound performed in follow-up of an antenatally detected right surprarenal mass demonstrates a solid, fairly homogeneous right adrenal mass lesion. Serial images failed to demonstrate involution over the course of several weeks. (b) Subsequent contrast-enhanced CT shows a solid homogenous right adrenal mass confirmed to be neuroblastoma upon excision.

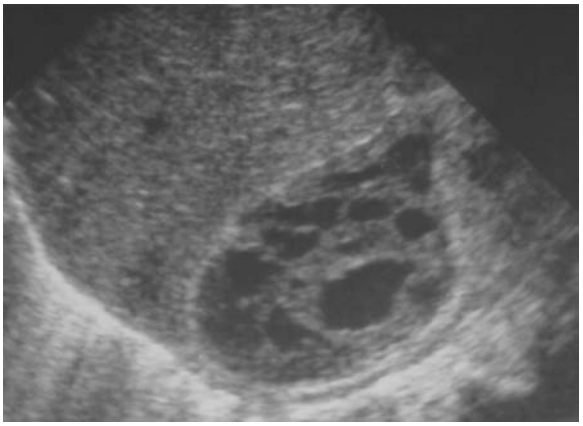

FIGURE 16.9 Ultrasound obtained in a 5-day-old neonate following traumatic delivery demonstrates a multiseptated right adrenal mass typical of an organizing hematoma.

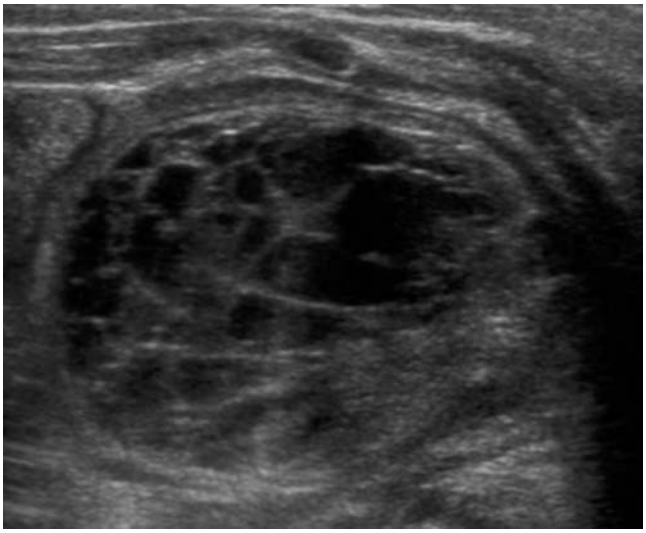

FIGURE 16.10 Sonogram on day 3 of life, requested to exclude renal anomalies in a patient with transposition of the great vessels. Unexpected but typical findings of a septated left adrenal hematoma. The incident causing the hematoma likely occurred in utero.

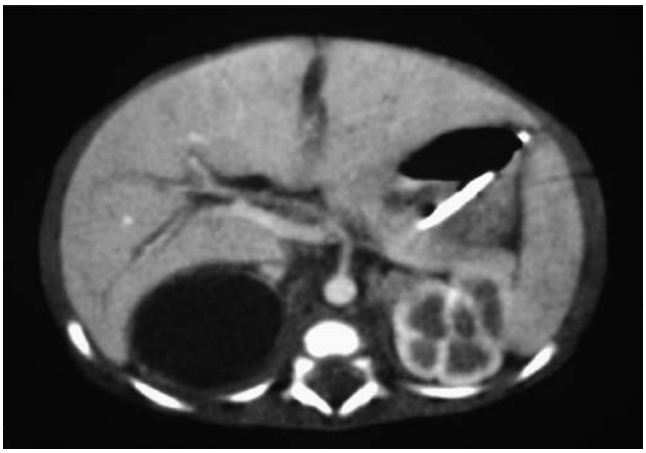

FIGURE 16.11 Contrast-enhanced CT on the same day as ultrasound in Figure 16.9. In the right adrenal location, a nonenhancing low-density mass typical of an adrenal hematoma is apparent. Note that the septations are not apparent on the CT.

CALCIFIED ADRENAL LESIONS

Adrenal calcification detected on abdominal imaging of a child has a broad differential diagnosis (Table 16.3), but it usually prompts investigations for a tumor, most commonly neuroblastoma.[39] The aforementioned affinity of neuroblastoma for skeletal tracer is independent of the presence of calcification, and its mechanism is unknown.[41] Ganglioneuromas and ganglioneuroblastomas can also calcify, and they are radiographically indistinguishable from neuroblastomas.

Granulomatous diseases often result in childhood adrenal calcification either unilaterally or bilaterally.[42–44] Distinguishing from the various granulomatous infections is impossible by imaging alone.

TABLE 16.3 Differential diagnosis of pediatric calcified adrenal masses

Neural crest tumors: Neuroblastoma[a] Ganglioneuroblastoma[a] Ganglioneuroma
Resolving hemorrhage[a]
Adrenal cortical carcinoma
Pheochromocytoma
Adrenal cortical adenoma
Granulomatous infection
Storage disorders: Wolman's disease Niemann–Pick disease
Myelolipoma

[a] Denotes most common findings.

Wolman's disease is an uncommon autosomal recessive inborn error of metabolism leading to the accumulation of lipid in the abdominal organs. The condition is usually fatal by 6 months of age. On plain film, the adrenal glands are enlarged and densely calcified. Ultrasound demonstrates concomitant hepatosplenomegaly. CT confirms the adrenal origin of the calcifications. MRI demonstrates the adrenal high signal intensity on T1 sequences due to lipid deposition.[45,46]

As mentioned above, perinatal adrenal hemorrhage can subsequently calcify. Imaging characteristics can vary from a peripheral rim of calcification to complete replacement of the gland. Incomplete resolution of hematoma can result in a peripherally calcified rim around a nonenhancing pseudocyst.[46]

CHAPTER 17

Adrenal Tumors and Functional Consequences

Melanie I. Morris, Julie Franc-Guimond, and Anne-Marie Houle

INTRODUCTION

The pathogenesis, diagnosis, and management of adrenal tumors have recently evolved.[1,2] This is mainly because of the earlier discovery of insidious, clinically silent tumors. There are increasing numbers of incidentally detected adrenal tumors due to the use of more sensitive imaging procedures, such as computed tomography (CT) and magnetic resonance imaging (MRI).[3] Although these tumors are rare in children, it is important that the physician recognizes the clinical manifestations of these tumors as soon as possible, leading to earlier diagnosis, prompt intervention, and improved survival.

EPIDEMIOLOGY

Adrenal neoplasms are fortunately rare in the pediatric population, representing less than 1% of all solid tumors. Despite their infrequency, however, they can be fatal. Tumors arise from the medulla or cortex of the adrenal gland and can be benign or malignant. Malignant tumors account for 0.05%–0.2% of all malignancies in the pediatric population, with an incidence of less than 2 new cases per 1 million per year.[4,5] Adrenocortical carcinomas (ACCs) occur at all ages[6–11] and tend to present according to a bimodal distribution. The first peak occurs before the age of 5 years, and the second peak occurs in the fourth to fifth decade.[12] Females clearly predominate in all series, accounting for 65%–90% of the cases reported in the literature.[2] The reasons for this preponderance in women are unknown. Some authors have reported a left-sided prevalence; however, others state that bilateralism has been observed in 2%–10% of cases.[2,9] The incidence of ACCs is approximately 1 in 1.7 million in the general population.[13] They are seen in older patients compared with adenomas[14] and are more frequently encountered in females.[6] Moreover, they tend to be functional and may be part of hereditary syndromes. A retrospective review revealed that 92% of patients found to have a carcinoma presented with mixed endocrine syndromes versus 32% of patients with an adenoma,[15] the latter group presenting with only a virilizing syndrome.

MASSES OF THE ADRENAL CORTEX

Cortical tumors may be benign or malignant, functional or silent, all of which are rarely seen in children.[16–18] The identification and evaluation of these lesions can be very challenging, as it is often difficult to distinguish between the different types. Histopathology is the definitive confirmation; however, at times the clinical outcome may not even correlate with the histologic features.[19] Adrenal masses are often found incidentally and are nonfunctional in the general population, but in children, most are functional, leading to a more challenging diagnosis and treatment.

Associated endocrine syndromes resulting from secretion of cortisol and/or adrenal androgens and their precursors, or, rarely, estrogen or mineralocorticoids, may be seen in patients with functional neoplasms. They can produce syndromes of hypercortisolism and hyperaldosteronism, and rarely produce virilization or feminization. A more gradual onset of signs of hormone hypersecretion is generally observed in patients with adenomas, unlike those with ACC, who tend to have a more acute and progressive course.

Cushing's Syndrome

Hypercortisolism, or Cushing's syndrome, describes any form of glucocorticoid excess, which leads to protein catabolism, subsequent increased gluconeogenesis, and the typical symptoms associated with cortisol excess. Cushing's syndrome refers to patients presenting with a constellation of symptoms and signs regardless of the cause. It differs from Cushing's disease, which is caused by pituitary hypersecretion of the adrenocorticotropic hormone (ACTH). Cushing's syndrome in children is most commonly caused by an ACC and is seen in one-third to one-half of these patients.[20] One-fourth of the cases of endogenous Cushing's syndrome are caused by primary adrenal disease.

Aside from functional adrenocortical tumors and other usual causes, Cushing's syndrome can be particularly seen in children with primary pigmented nodular adrenocortical disease, which occurs as a component of Carney's complex. Also, infants found to have the McCune–Albright

syndrome can present with ACTH-independent Cushing's syndrome with nodular hyperplasia or adenoma formation. Finally, islet cell carcinoma of the pancreas, neuroblastoma or ganglioneuroblastoma, hemangiopericytoma, Wilms' tumor, thymic carcinoid, medullary thyroid cancer, and pulmonary neoplasms can lead to ectopic production of ACTH in the pediatric population.

Pathophysiology

ACTH is secreted in response to the corticotropin-releasing hormone (CRH) and vasopressin. It stimulates glucocorticoid cortisol secretion from the zona fasciculata and zona reticularis of the adrenal gland. The ensuing increased serum cortisol creates negative feedback on CRH, vasopressin, and subsequently ACTH. The amplitude and duration, but not the frequency, of ACTH secretory episodes are increased in Cushing's disease and the normal ACTH circadian rhythm is usually lost.[21] Cushing's syndrome occurs when there is a loss of the feedback mechanism of the hypothalamic–pituitary–adrenal axis, resulting in chronic exposure to excess circulating cortisol.

Constitutive activation of β-catenin has now been identified as a frequent alteration in benign and malignant adrenocortical tumors. The Wnt/β-catenin pathway is suggested to be essential in the development of the adrenal.[22] The ectopic constitutive activation could be associated with adrenal tumorigenesis considering the increased occurrence of adrenal tumors in patients with mutations of adenomatous polyposis coli (APC).[23] In a larger study including 100 surgically removed adrenal adenomas (excluding aldosteronomas), abnormal cytoplasmic and/or nuclear β-catenin immunohistochemical staining was found in about half; 36% had CTNNB1 mutations, mostly in larger and nonsecreting adenomas, suggesting that the Wnt/β-catenin pathway activation is associated with the development of less differentiated tumors.[24]

Clinical Findings

Signs and symptoms associated with hypercorticosolemia are variable. An important clinical manifestation is the simultaneous development and increasing severity of several of these symptoms. Typical symptoms and signs include moon facies, truncal obesity, and wide purplish striae. The most frequent and reliable findings in children with Cushing's syndrome are weight gain and growth failure,[25] and should highlight the possibility of the diagnosis.[6] Other findings may include hirsutism, muscle weakness, bruising, vertebral fractures, hypertension, and diabetes mellitus, but these are rarely seen. Lethargy, depression, acne, and menstrual irregularity[26,27] are other features observed. Patient's photographs may help in showing the clinical progression to a cushingoid state. In general, the clinical manifestation is more important in infants than in older children.

Laboratory Findings

Determining the presence of Cushing's syndrome is more important initially than identifying the cause.[28] Cushing's syndrome due to functioning adrenocortical tumors will exhibit elevated levels of several plasma and urinary steroids. These include cortisol following dexamethasone suppression test; dehydroepiandrosterone (DHEA) and its sulfate derivative (DHEAS); Δ^5-androstenediol, Δ^4-androstenedione, pregnenolone, 17-hydroxypregnenolone, and 11-deoxycortisol in the plasma; and free cortisol, 17-hydroxysteroids, 17-ketosteroids, and the tetrahydro metabolite of 11-deoxycortisol in the urine.[26] Measurements of other steroidogenic precursors, such as 17-hydroxyprogesterone and 11-deoxycortisol, may help if the presence of an adrenal malignancy in the patients with Cushing's syndrome is suspected.[27] Autonomous activity of the adrenal glands will lead to a low plasma ACTH level, associated with elevated plasma cortisol concentration.

Tumor Localization

Abdominal CT and/or MRI can document the existence of an adrenal lesion or bilateral nodular hyperplasia in cases of ACTH-dependent Cushing's syndrome. In patients with adrenal tumors, the contralateral adrenal should appear normal but could be atrophic since there is suppression of ACTH by the unilateral cortisol-secreting tumor.[29] It is often irresolute to determine between adenomas and carcinomas; however, tumors larger than 5 cm should be considered malignant until proven otherwise. Nevertheless, the diagnosis is ultimately confirmed by histopathology.[30,31]

Treatment

The treatment of Cushing's syndrome secondary to adrenal tumors is surgical. Unilateral adrenalectomy is performed for masses; however, bilateral adrenalectomy is completed for ACTH-dependent Cushing's syndrome not cured by other modalities. Measures to correct the hypercortisolemia and its metabolic sequelae are essential in preoperative preparation. Moreover, cortisol administration perioperatively should be given to prevent a state of hypoadrenalism. This is especially important in cases of total bilateral adrenalectomy, but also in cases of unilateral adrenalectomy, as the removal of the source of excessive cortisol in the presence of an invariably atrophied contralateral gland will inevitably lead to temporary or permanent adrenal insufficiency.

Medical treatment is indicated in patients who cannot undergo surgery or in those who have had unsuccessful resection of their tumor (pituitary, ectopic, or adrenal) with or without metastatic spread. Metyrapone, ketoconazole, aminogluthimide, mitotane, and etomidate have been used as inhibitors of steroid biosynthesis, and thus can be utilized in all cases of hypercortisolemia, regardless of cause, often with rapid improvement in the clinical features.

Prognosis

Surgical resection of an adenoma offers an excellent prognosis, whereas the outlook for patients with malignant tumors is poor. Children tend to have a better prognosis.[32,33]

Hereditary Syndromes

Although most cases of ACC appear to be sporadic, there are some that are associated with hereditary

cancer syndromes.[34] Multiple endocrine neoplasia type 1 (MEN 1) (parathyroid, pituitary, and pancreatic neuroendocrine tumors and adrenal adenomas or carcinomas) is connected to the inactivation of the MEN 1 gene on chromosome 11q. In addition, Beckwith–Wiedemann syndrome is associated with Wilms' tumor, neuroblastoma, and hepatoblastoma, and ACC is also linked with abnormalities in 11p15. Li–Fraumeni syndrome, which is related with inactivating mutations of the TP53 tumor suppressor gene on chromosome 17p, is associated with ACC in addition to breast cancer, soft tissue and bone sarcoma, and brain tumors. Finally, the SBLA syndrome, including sarcoma, breast and lung cancer, ACC, and other tumors, has not been localized to any chromosome.

Hyperaldosteronism

Aldosterone is the principal mineralocorticoid secreted by the adrenal gland. Increased secretion may be secondary to a primary defect (primary hyperaldosteronism) or result from factors that activate the renin–angiotensin system (secondary hyperaldosteronism).[94–96] Patients with primary hyperaldosteronism present with hypertention and/or hypokalemia; those with secondary hyperaldosteronism do not. Primary aldosteronism will lead to a state of mineralocorticoid excess with low plasma renin activity (PRA). It may be caused by the following pathologies: an aldosterone-producing adenoma (APA), idiopathic bilateral (BAH) or unilateral (UAH) adrenal hyperplasia, glucocorticoid-remediable aldosteronism (GRA), or rarely, an aldosterone-producing ACC. Adrenocortical hyperplasia is the most common cause in children.[8]

Although uncommon, unilateral APA has been described in children as young as 3.5 years and affects girls more frequently than boys. In 1954, Conn first reported that hypertension, hypokalemia, and metabolic alkalosis result from autonomous production of aldosterone by an adenoma. Since then, numerous studies have looked at the prevalence of primary aldosteronism and reported rates between 0.05% and 14.4% among hypertensive individuals.[35–38] BAH tends to occur in older children and affects males more frequently. Primary aldosteronism due to UAH has been reported infrequently in the pediatric population.[39–43] Adrenal carcinomas, an exceedingly rare cause of primary aldosteronism, are usually large (>5 cm) at the time of diagnosis.

Other states of mineralocorticoid excess with low PRA may include cases of congenital adrenal hyperplasia or Liddle's syndrome.[44] In these two syndromes, non-aldosterone-mediated renal sodium reabsorption results in volume expansion and suppression of both PRA and plasma aldosterone (PA).

At the other end of the spectrum, other patients may present with a state of mineralocorticoid excess with high PRA. They may be hypertensive (renovascular disorders, coarctation of the aorta, or renin-secreting tumors) or normo- or hypotensive with reduced circulating blood volume (Gitelman's syndrome, Bartter syndrome, pseudohypoaldosteronism type 1, or diuretic use), or have a reduced "effective" circulating blood volume (congestive heart failure, hepatic cirrhosis, or nephrotic syndrome).

Physiology of Aldosterone

Aldosterone synthesis is orchestrated by the renin–angiotensin system. Renin, produced in the juxtaglomerular apparatus, catalyzes the conversion of the angiotensinogen to angiotensin I. Angiotensin I undergoes further enzymatic conversion by angiotensin-converting enzyme (ACE) to produce angiotensin II, which acts to stimulate the production of aldosterone from the zona glomerulosa. The renin–angiotensin II system is also expressed locally and regulates aldosterone production in a paracrine fashion. Aldosterone's release is positively and directly modified by potassium balance. It can also be modulated by other factors, such as ACTH, dopamine, and atrial natriuretic peptide.

Clinical Findings

Signs and symptoms of hyperaldosteronism are nonspecific, often resulting in or associated with hypertension with headache, dizziness, and visual disturbances. However, some individuals have minimal elevation of blood pressure. Therefore, hypertension is not a sine qua non for this disorder.[12] In reality, the most common finding remains hypokalemia. Chronic hypokalemia may lead to "clear cell nephrosis," polyuria, nocturia, enuresis, and polydipsia. Muscle weakness and discomfort, tetany, intermittent paralysis, fatigue, and growth failure may also be observed in these children. Classic features of moderate to severe hypertension, hypokalemia, and metabolic alkalosis are highly suggestive of mineralocorticoid excess. However, only subtle clues of hyperaldosteronism exist in the majority of cases, such as the recent onset of refractory hypertension.

Laboratory Findings

Hyperaldosteronism can generally be proven by measurements of aldosterone and PRA, 11-deoxycorticosterone, and/or corticosterone, respectively. Plasma and urine levels of aldosterone are increased, and plasma levels of renin are persistently low.[35–37] In addition, the serum pH, carbon dioxide content, and sodium concentrations may be increased, and the serum chloride and magnesium levels can be decreased. Serum levels of calcium are normal, even in children who manifest tetany. The urine is neutral or alkaline, and kaliuresis is present. Aldosterone does not decrease with sodium chloride administration, and renin does not respond to salt and fluid restriction.

Differential Diagnosis and Tumor Localization

All cases with a history of hypertension associated with "spontaneous" or severe hypokalemia precipitated by diuretic therapy should suggest the diagnosis of primary aldosteronism. Suspicion is also warranted in all incidentally discovered adrenal masses, especially in a hypertensive individual.[45] Once the diagnosis is established, it is necessary to identify the underlying cause (APA, BAH, UAH, GRA, or an aldosterone-producing ACC).

All children should have a therapeutic trial with daily administration of dexamethasone before invasive studies are carried out, since this test is easy to perform. A marked

suppression of aldosterone and disappearance of hypertension is observed in patients with the glucocorticoid-suppressible variant of hyperaldosteronism or GRA.

If there is no response, CT scanning or MRI may reveal a mass within the adrenal. In cases of inconclusive data or equivocal radiographic features, however, adrenal vein sampling of aldosterone and cortisol is recommended to differentiate between an adenoma and hyperplasia.[46–49]

Treatment

GRA is managed by daily administration of glucocorticoid. The treatment of a functional adenoma is excision. Resection is frequently curative or improves hypertension and invariably treats the hypokalemia. In one recent analysis, however, only one-third of patients became normotensive postoperatively.[50] In patients known to have an APA, suppression of aldosterone secretion in the contralateral adrenal gland is expected, thus resulting in a transient hyporeninemic hypoaldosterone state.[51] Therefore, sodium restriction could increase the risk of dehydration. Pharmacologic treatment of BAH with spironolactone or amiloride usually results in normalization of the blood pressure and serum potassium levels. Management of secondary hyperaldosteronism is directed toward the specific causative agent.

Virilizing Tumors

Abnormal virilization is seen in cases of ACC in two-thirds of the adult patients,[52] whereas it is the most common hormonal syndrome in children with adrenocortical tumors.[2,8,10,53] Virilization is due to hypersecretion of adrenal androgens, including DHEA and DHEAS, Δ^5-androstenediol, and Δ^4-androstenedione, all of which may be converted to testosterone and 5α-dihydrotestosterone.

In adult females, the signs and symptoms include oligoamenorrhea, hirsutism, acne, excessive muscle mass, temporal balding, increased libido, and clitoromegaly. In young girls, precocious puberty occurs. Cushing's syndrome, combined with signs of virilization, is seen in 10%–30% of all patients.[2,3,54]

Measurement of plasma adrenal androgens, testosterone, and 24 h urinary excretion of 17-ketosteroids may confirm the clinical diagnosis of adrenally induced virilization.

Androgen-secreting adrenal tumors are usually malignant, but benign tumors have also been described in women. In a series of 21 women with androgen-secreting tumors, malignant tumors ($n = 10$) were larger at presentation than benign tumors ($n = 11$; 14 vs. 9 cm, respectively). Moreover, in women with malignant tumors, serum testosterone levels were 2.6-fold higher.[55] In benign cortisol-secreting adenomas, serum androgen levels are usually not high but can produce small amounts of androgen.[56]

Feminizing Adrenal Tumors

Estrogen-secreting tumors are rare and are usually malignant.[57] In males, they can present as feminization with gynecomastia, decreased libido, and testicular atrophy; in women, they can present with breast tenderness and dysfunctional uterine bleeding. They can be confirmed by measurements of elevated plasma estradiol and/or estrone.[58]

MASSES OF THE ADRENAL MEDULLA

Pheochromocytoma

Pheochromocytomas are rare neoplasms in children. They are neuroendocrine tumors that arise from neural crest–derived chromaffin cells in the adrenal medulla. During embryologic development, chromaffin cells migrate to the adrenal medulla. Pheochromocytomas are catecholamine-secreting tumors. Ninety percent arise from the medullary portion of the adrenals, whereas 10% occur in extra-adrenal chromaffin tissues (paragangliomas). About 10% are familial, multicentric, and bilateral, whereas the remainder are sporadic. The incidence in the hypertensive population varies between 0.05% and 0.1%.[99]

Pheochromocytomas are uncommonly observed in children, and the true incidence is unknown. Indeed, it appears that this tumor of neuroectodermal origin is more common in adults. Most of what is known on the behavior and management of these tumors arises from the adult literature. In children, the age of presentation is around 10 years; there is a male propensity in most series, an increased incidence of bilaterality (20%) and multifocality, a lower incidence of malignancy (2.4%–3.5%), and a greater tendency for familial occurrence.[59]

Familial pheochromocytomas can occur with or without an association to known familial cancer syndromes (MEN 2, von Hippel–Lindau disease, neurofibromatosis type 1, Sturge–Weber syndrome, and familial carotid body tumors).[60] It appears that hereditary forms can evolve differently in terms of tumor growth rate and malignancy potential. Thus, individuals with familial pheochromocytomas are diagnosed at a younger age and tend to have bilateral or multifocal lesions that are usually benign.

Signs and Symptoms

Signs and symptoms are related to excessive tumor secretion of catecholamines produced in large amounts by pheochromocytes. Hypertension is the most common sign, and in children, it is more sustained than paroxysmal symptoms. Other signs and symptoms could include postural hypotension, headaches, increased sweating, pallor, flushing, tachycardia, weight loss, constipation, weakness, and visual anomalies. The symptoms most frequently observed in children include headaches, nausea, vomiting, constipation, weight loss, and visual complaints.[61,62] A palpable mass and sustained hypertension are strongly suggestive of the diagnosis. However, a palpable mass may be the sole finding.

Diagnosis

The biochemical diagnosis is made from the measurements of catecholamines and catecholamine metabolites in plasma or urine.[63–67] Norepinephrine and epinephrine are produced by the sympathoneuronal and sympathomedullary

systems, and therefore are not specific to pheochromocytomas. Other limitations relate to the fact that increased plasma catecholamine levels may be produced by a variety of conditions (e.g., emotional stress, physical activity, eating, and fever). Some pheochromocytomas may not secrete catecholamines at all or may secrete them episodically. Glucagon stimulation and clonidine suppression tests are useful in some patients to further confirm the diagnosis of pheochromocytoma.[61,68,69]

Tumor Localization

Pheochromocytomas can be imaged with CT, MRI, and/or scintigraphy after administration of ^{131}I- or ^{123}I-labeled metaiodobenzylguanidine (MIBG).[70–73] If an initial abdominal CT or MRI is positive, whole-body MIBG should be performed to confirm the diagnosis. If abdominal studies are negative, then the whole-body evaluation by CT or MRI is indicated. If an initial MIBG scan is positive, then CT or MRI follows to more precisely localize a mass. However, a negative MIBG scan does not exclude a pheochromocytoma. More recently, positron emission tomography (PET) has been used in particular cases.

Treatment

The definitive treatment of pheochromocytoma is surgical excision of the tumor. Of particular interest, patients with pheochromocytomas should undergo pharmacologic blockade (α and β) of catecholamine effects and synthesis prior to surgery, as well as aggressive correction of the hypovolemia perioperatively to avoid hypotension. Intraadrenal pheochromocytomas can be removed successfully by laparoscopy, which minimizes catecholamine-induced hemodynamic changes during operation.[74]

Neuroblastic Tumors

Neuroblastic tumors will be briefly reviewed in this chapter. Neuroblastic tumors include ganglioneuroma, ganglioneuroblastoma, and neuroblastoma, which are tumors of the sympathetic nervous system.[75] They arise wherever sympathetic tissue exists and are found in the neck, posterior mediastinum, adrenal gland, retroperitoneum, and pelvis. The adrenal gland is the most common site.[100,118]

The most benign tumor is the ganglioneuroma, which is composed of gangliocytes and mature stroma.[76,77] It arises from the medulla in less than half of the cases found to have an abdominal ganglioneuroma.[78–81] Patients of all ages are affected, predominantly children and young adults (42%–60% of cases),[75–85] and they are often asymptomatic. Otherwise, abdominal pain or abdominal mass is the most common finding.[74] Hormonally active tumors have been reported, and the secretion of catecholamines, vasoactive intestinal polypeptides, or androgenic hormones explains such symptoms as hypertension, diarrhea, and virilization.[82–84,86–88] The prognosis is excellent, and recurrence is rare after surgical removal.[83,89]

Ganglioneuroblastomas are transitional tumors of sympathetic cell origin that contain elements of both malignant neuroblastoma and benign ganglioneuroma. The most common tumor location is the abdomen. This tumor is most often seen in patients who are 2–4 years old and is rarely seen after 10 years.[90] The prognosis and response to therapy are significantly more favorable than with neuroblastomas.[91]

Neuroblastoma is the most immature, undifferentiated, and malignant tumor of the three that consist of primitive neuroblasts.[92] Neuroblastomas, which account for 97% of all neuroblastic tumors, are heterogeneous, varying in terms of location, histopathologic appearance, and biologic characteristics.[93] They are most remarkable for their broad spectrum of clinical behavior, which can range from spontaneous regression to aggressive disease with metastatic dissemination leading to death.[94,101–112,119]

METASTATIC LESIONS

Metastatic lesions to the adrenal gland are uncommon, but when present, they tend to have an irregular shape and are inhomogeneous in nature. They have a tendency to be bilateral and have high unenhanced CT attenuation values, enhancement with intravenous contrast, and delay in contrast washout. They can include leiomyosarcomas, lymphoma, malignant melanoma, squamous cell carcinoma of the lung, hepatocellular carcinoma, and breast cancer.[97,98,112,115]

CHAPTER
18

Surgery of the Adrenal in Pediatric Patients

Jennifer E. Reifsnyder and Dix P. Poppas

INTRODUCTION

Adrenal surgery has an extensive and constantly evolving history, beginning with the first description of an adrenalectomy in 1914 by British surgeon Perry Sargent.[1] Since that time, understanding of the physiology and pathophysiology of the adrenal gland has become better understood, while advances in imaging of the adrenal gland have improved disease localization. The surgical approaches have also evolved with the advent of and improvements in minimally invasive surgery (MIS). The spectrum of pediatric adrenal disease and the pathophysiology governing these processes have been covered in previous chapters. The focus of this chapter is on the surgical management of adrenal disease, with special consideration for the development of minimally invasive techniques in pediatrics.

MINIMALLY INVASIVE ADRENALECTOMY

Endoscopic surgery in pediatric patients dates back to 1971, when Gans and Berci[2] investigated and reported on a case series of minimally invasive procedures on infants and children. Since then, the types and quantity of MISs have increased, with significant advancements in technology and proficiency. Laparoscopic adrenalectomy was first described by Gagner et al. in 1992,[3] and since then has rapidly replaced open adrenalectomy (OA) as the criterion standard for adrenal surgery in adults.[4–9] Multiple large studies have found that minimally invasive adrenalectomy (MIA) is associated with decreased length of hospital stay, decreased operative times, decreased reoperation rates, decreased postoperative complications, and decreased morbidity rates even after adjustment for confounding factors.[4,5,10]

However, these results should not necessarily be applied to the pediatric population because of significant differences in patient characteristics, including comorbidities and patient size, and in the rates of benign versus malignant tumors. Neuroblastoma, which represents the most common adrenal tumor in children, is characterized by an infiltrative growth pattern that was originally seen as a contraindication to MIA. However, continued experience with laparoscopy and robot-assisted surgery, along with continued improvements in surgical instrumentation, has expanded the indications for and use of MIA in pediatric adrenal surgery.

The largest pediatric studies involving MIA demonstrate a low morbidity rate ranging from 0% to 10% for well-encapsulated masses without image-defined risk factors (IDRFs).[11–15] Port site recurrence of cancerous tumors has not been described in any children after MIA.[16] Children undergoing MIA have a significantly shorter length of stay than those undergoing OA.[17] MIA may also provide several potential advantages over OA, including decreased rates of intestinal obstruction, decreased levels of postoperative pain, and improved cosmetic results. The rates of postoperative intestinal obstruction are significantly lower after MISs (0.9%)[18] than after open abdominal tumor surgeries (3.7%).[18,19] Although improved postoperative pain control has been assumed to be an advantage of MIS in comparison with open procedures in pediatric populations, several randomized controlled trials found no significant differences in pain control.[20–22] However, these trials were for short procedures with small parietal incisions (e.g., appendectomy, pyloromyotomy, and pyeloplasty). OA is performed with a large transperitoneal incision compared with the subcentimeter incisions with MIA, which could potentially lead to significantly decreased postoperative pain levels. In addition, long-term cosmetic results can have a significant impact on the quality of life in children who survive a malignant tumor. MIA has a significant advantage in this regard, with 5 or 10 mm incisions compared with the large transperitoneal incisions utilized for OA.

APPROACHES TO MINIMALLY INVASIVE ADRENALECTOMY

MIA can have significant advantages over OA in children for well-encapsulated masses without IDRFs. MIA can be performed using multiple approaches, including the transperitoneal adrenalectomy (TA) and prone retroperitoneal (PRA), and lateral retroperitoneal (LRA) approaches, as well as robot-assisted adrenalectomy (RAA) and single-port techniques. We will discuss each of these approaches, and comment on their advantages.

Laparoscopic Transperitoneal Adrenalectomy

Patients are placed on a clear liquid diet the day prior to surgery and given a mechanical bowel preparation. After the patient is intubated, a Foley catheter is inserted into

the bladder, and the stomach is decompressed with an oral gastric tube. We place the patient in a semilateral decubitus position, with the side of the lesion elevated approximately 45°, and flex the operating table. The patient is draped from the nipple line to the lower abdomen and across the midline, allowing for possible open conversion. The patient is rolled to a near-supine position, and pneumoperitoneum is established. We prefer the Hasson open, cut-down technique for establishing the pneumoperitoneum in the pediatric population. The first trocar, an 11–12 mm trocar, is placed in the midline just above the umbilicus. The peritoneal space is insufflated to 12–15 mmHg using CO_2, and the abdominal cavity is explored with a 10 mm, 30° laparoscope. The table is then rolled to a full flank position for additional trocar placement.

For left TA, two accessory trocars are inserted: a 5 mm port 3–4 cm cephalad to the supraumbilical trocar, and a 5 mm port in the midclavicular line, below the costal margin (Figure 18.1). Port placement may vary slightly with the age and size of the child. Adhesions of the left upper quadrant to the anterior abdominal wall are first identified and incised using the harmonic scalpel. The splenic flexure of the left colon is then mobilized by incising the peritoneum along the line of Toldt. The spleen is mobilized by incising its attachments to Gerota's fascia, the abdominal side wall, and the diaphragm with the harmonic scalpel or electrocautery shears. Dissection of the lateral splenic attachments is carried out until the gastric fundus is visualized. At the conclusion of this dissection, the spleen should fall medially without the need for retraction.

Once the splenic flexure and spleen are mobilized, the plane between the tail of the pancreas and Gerota's fascia is developed to release the pancreas medially. The superior border of the adrenal gland is then dissected from lateral to medial. The inferior phrenic vessels are identified, clipped, and divided as they are encountered along the upper aspect of the adrenal. The lateral-most attachments of the gland are left intact to hold the gland in place and thereby facilitate the remainder of the dissection. Dissection is continued medially along the gland, where the arterial supply to the adrenal from the aorta is encountered, clipped, and divided. Inferiorly, the left adrenal vein is identified entering the left renal vein, clipped, and divided.

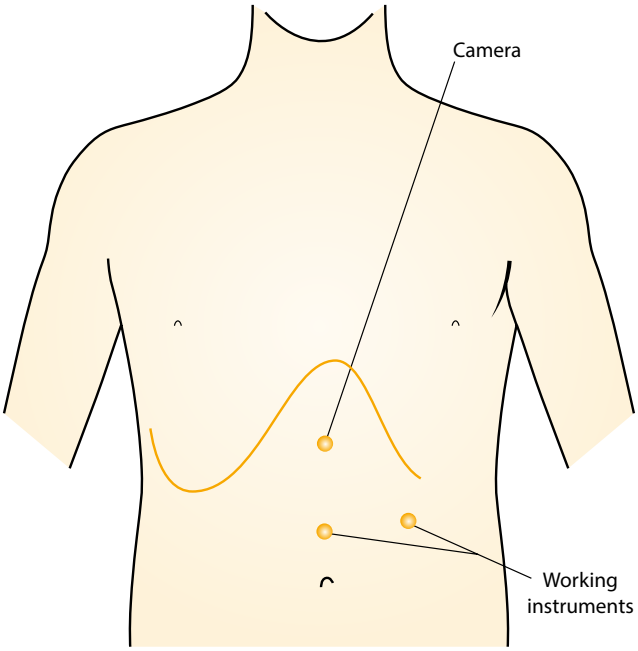

FIGURE 18.1 Port placement for transperitoneal laparoscopic left adrenalectomy. The supraumbilical working instrument is 11–12 mm, to facilitate insertion of a clip applier.

Division of the left adrenal vein often reveals an inferior adrenal artery arising from the left renal artery; if encountered, this artery should be clipped and divided. Finally, the lateral attachments of the adrenal are divided, releasing the gland. The adrenal is placed in a retrieval bag inserted through the umbilical port. Visualization for the remainder of the procedure is accomplished with a 5 mm, 30° scope placed through the port in the midclavicular line. The bag containing the specimen is temporarily placed on the kidney, and the operative bed irrigated and inspected for bleeding. Once hemostasis is ensured, the specimen is then removed from the patient; the trocar site may be enlarged if necessary to facilitate the removal of larger glands. The remaining ports are then removed and closed.

Laparoscopic right TA is performed using three accessory trocars, because of the need to retract the liver. After insufflations, a 5 mm port is placed 3–4 cm cephalad to the supraumbilical trocar (as for the left adrenalectomy), while two 5 mm ports are placed laterally below the costal margin in the anterior axillary and midclavicular lines. After adhesions of the right upper quadrant to the anterior abdominal wall are incised, the liver is mobilized from the abdominal side wall and diaphragm by incising the triangular and coronary ligaments. The extent of mobilization of the liver necessary for exposure increases with age in children, as the distance between structures increases and the flexibility of tissues decreases. A liver retractor is then introduced through the anterior axillary line trocar to reflect the liver away from the adrenal (Figure 18.2). With the liver mobilized, the anterior wall of the vena cava is identified, and the medial attachments of the adrenal gland are released. The duodenum is mobilized medially, exposing the renal hilum. As the dissection is carried cephalad on the anterior wall of the cava, the right adrenal vein is identified. We secure the vein by doubly clipping both the patient and specimen sides of the vein and then sharply dividing the vein between the clips (Figure 18.3). Once the adrenal vein has been controlled, the superior and inferior aspects of the adrenal are sequentially dissected as for a left adrenalectomy, dividing the inferior vascularized pedicle, which arises from the right renal hilum, on the caudal border of the gland. The adrenal gland is then mobilized off the upper pole of the kidney by incising Gerota's fascia at the junction of the upper pole and adrenal using the harmonic scalpel. The lateral attachments, left intact to maintain the gland in position for dissection, are released last, and the adrenal removed.

Postoperatively, patients are started on clear liquids on the night of surgery, and their diet is advanced as tolerated. The Foley catheter is removed on the first postoperative day, and patients are typically discharged after passing a trial of voiding.

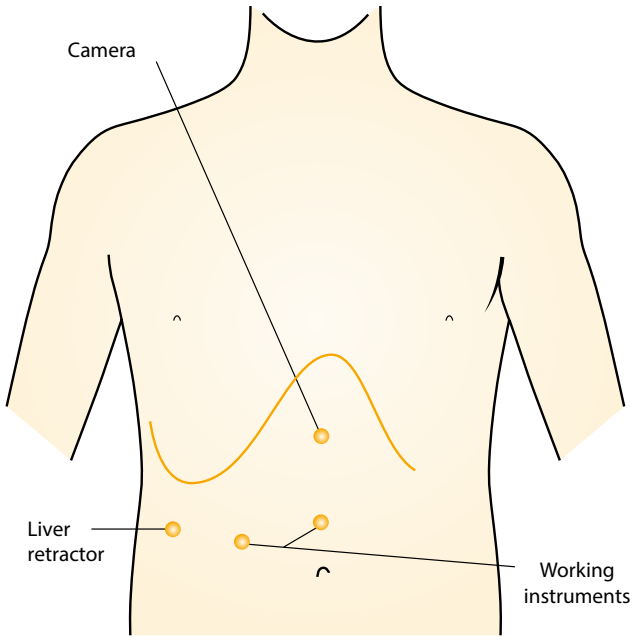

FIGURE 18.2 Port placement for transperitoneal laparoscopic right adrenalectomy. Note the additional trocar in the anterior axillary line for liver retractor.

Prone Retroperitoneal Adrenalectomy

The patient is placed in a fully prone position, with attention paid to place the patient close to the border of the operative table on the side of the operation in order to provide full range of motion of the lateral port. The thorax and pelvis are elevated to free the abdomen. The initial incision is made halfway between the iliac crest and the 12th rib at the lateral border of the vertebral muscles.

The retroperitoneal space outside Gerota's fascia is dissected out. The working space in the retroperitoneum is established using balloon distention. We prefer fashioning a balloon for distention by securing the finger of a surgeon's glove to a 16 Fr red rubber catheter. Once the balloon is introduced into the retroperitoneal space, the glove tip is filled with 100–500 cc of saline and left inflated for 5 minutes to develop the retroperitoneal space. The balloon is then removed and a 10 mm Hasson trocar is introduced into the space and pneumoretroperitoneum established to a pressure of 12 mmHg. Two additional ports are then placed, a 3 mm port at the tip of the 12th rib and a third 5 mm port between the two prior ports.

The same landmarks are used for dissection as in TA, with care to identify the inferior vena cava (IVC) on the right side, and the splenic and renal veins on the left. The specimen is then delivered through the medial incision.

Retroperitoneal laparoscopy has been well described for a variety of procedures in adults since the initial description by Gaur.[23] The potential advantages of the retroperitoneal approach include more direct access to the adrenal glands, easier identification of the vascular landmarks, decreased risk of injury to the intra-abdominal organs, safety in patients who had prior abdominal trauma or surgery, and the possibility of bilateral procedures in one surgical position. However, there are significant disadvantages that must be taken into account. There is a more limited working space, which is a particular challenge in the pediatric patient population.[24] In addition, pediatric surgeons are much less familiar with this approach. The largest adult study of PRA in 520 patients by Walz et al.[25] found that there is a significant learning curve in PRA, and that there was a continuous decrease in operative time as the surgical experience increased.

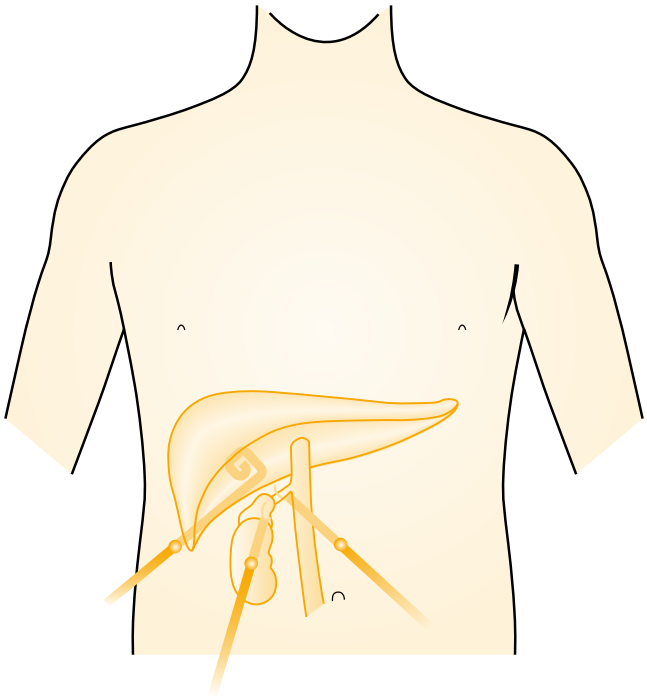

FIGURE 18.3 Transperitoneal laparoscopic exposure and ligation of the right adrenal vein.

Lateral Retroperitoneal Adrenalectomy

We position the patient in a flank position, and gain initial access through an incision below the tip of the 12th rib, just superior to the anterior iliac spine. Dissection is carried out bluntly through the external and internal oblique muscles and the transversus abdominus muscle into the retroperitoneum. The peritoneum is swept medially, and a working space in the retroperitoneum is established using balloon distention. The retroperitoneum working space is opened in a fashion similar to that of the PRA approach, with a modified homemade balloon. A 10 mm Hasson trocar is introduced into the space, and the pneumoretroperitoneum established to a pressure of 12 mmHg. Two additional 5 mm trocars are placed in the posterior and anterior axillary lines, superior to the Hasson trocar. For right adrenalectomy, the vena cava is identified medial to the psoas muscle, and dissection is carried superiorly along the vena cava to identify first the renal hilum and then the right adrenal vein, which is ligated using hemoclips. The medial and inferior margins of the adrenal are dissected, dividing the adrenal arteries with the harmonic scalpel or clips as they are encountered. The superior aspect of the gland is mobilized as well, and the adrenal is then

dissected free from the upper pole of the kidney. As with the TA, the lateral attachments of the gland are released last, and the adrenal is removed.

The initial dissection for a left LRA identifies the renal hilum. The left renal artery is retracted inferiorly, revealing the adrenal vein as it enters the left renal vein. The adrenal vein is ligated with hemoclips and divided. The adrenal gland is then dissected along its perimeter, using the harmonic scalpel and hemoclips as needed. For a left-sided LRA, the medial attachments of the gland are left intact to facilitate dissection, while the superior, lateral, and inferior mobilization of the adrenal is completed. The medial attachments are released last, and the specimen is removed.

Robot-Assisted Adrenalectomy

The first RAA was reported by Piazza et al.[26] in 1999 using the Zeus AESOP system. Since then, major improvements in the technology and increasing familiarity with minimally invasive techniques have allowed for broader applications of robot-assisted procedures. The first RAA was described by Horgan and Vanuno[27] using the da Vinci® Surgical System (Intuitive Surgical, Sunnyvale, California). Robot-assisted surgery provides the surgeon with magnified three-dimensional vision, seven degrees of freedom, scaling of movement, and minimization of tremor, which make this technology ideal for pediatric patients.

Multiple case series have found that RAA can be performed safely with lengths of stay and complication rates comparable to those of open and other laparoscopic procedures.[28–33] In one of the largest series of 100 consecutive adult patients, Brunaud et al.[33] found that RAA could be safely performed with low complication rates. For technically difficult masses, such as large adrenal masses greater than 5 cm, RAA may provide a benefit compared with laparoscopic techniques; Agcaoglu et al.[29] found that those undergoing RAA had significantly shorter operative times, shorter hospital stays, decreased open conversion rates, and lower complication rates. Conversely, Morino et al.[34] performed a small, randomized controlled trial comparing RAA with laparoscopic adrenalectomy that showed a higher open conversion rate for RAA. A meta-analysis by Brandao et al.[35] concluded that operative time and open conversion rates are similar between RAA and laparoscopic adrenalectomy, while blood loss and hospital stay were improved for RAA. As there have been no well-powered randomized controlled trials comparing RAA with laparoscopic adrenalectomy or OA in the adult or pediatric population, a direct comparison of outcomes among series is potentially biased. Future studies will be needed to clearly define the role of robotic surgery, especially in pediatrics.

The costs involved with the instrumentation are more expensive for the robotic procedure than for traditional laparoscopy.[33] However, with significantly shorter hospital stays and decreased pain requirements, the overall hospital costs of RAA are similar to, if not significantly less than, traditional laparoscopy. In addition, when accounting for the human capital calculations, especially regarding loss of parental workdays and loss of potential wages, robot-assisted surgeries could have significant advantages over other techniques.[36]

RAA can be performed through any of the previously mentioned laparoscopic approaches, the PRA, transabdominal adrenalectomy, or LRA. In the retroperitoneal approach, the patient is placed in a jackknife position with the use of a Wilson frame. A transcutaneous ultrasound can be used to map out the location of the ipsilateral kidney, 12th rib, and adrenal gland. An incision is made 2 cm inferior and parallel to the 12th rib. An optical trocar can then be placed to enter Gerota's space, and the working space can be defined by a 10 mm dissecting balloon under direct vision. This trocar can then be replaced by a 12 mm long trocar, with insufflations kept between 15 and 20 mmHg. Two 5 mm trocars are then inserted on either side of the trocar, taking care to optimize the distance between the trocar and camera port to avoid port site conflicts. The operating table is then rotated 30° clockwise, and the robot is brought in from the head of the table. A robotic grasper is then placed in the medial port and a robotic harmonic scalpel in the lateral port. The dissection can then continue from the superolateral border to the inferior border, and finally to the medial border. The adrenal vein is then identified and divided between two 5 mm clips placed by an assistant.

In the transperitoneal approach, the patient is placed in a semilateral decubitus position with either a bean bag or roll. We prefer the Hasson open, cut-down technique for establishing the pneumoperitoneum in the pediatric population; however, other techniques, such as the Veress needle, can also be used. A 10 mm trocar is placed in the midline just above the umbilicus. The peritoneal space is insufflated to 12–15 mmHg using CO_2. Two 5 mm robotic ports can then be placed, one port 1 cm inferior to the costal margin in line with the optical port, and another 3 cm inferior to the optical port in the midclavicular line. One additional 5 mm port can be inserted for bedside laparoscopic assistance.

Single-Port Techniques

Laparoscopic single-port surgery, called laparoendoscopic single-site (LESS) surgery, single-port access (SPA), or single-incision laparoscopic surgery (SILS), depending on the manufacturer, has been increasingly used as comfort and experience with laparoscopy continues to improve and the instruments continue to improve. Compared with robot-assisted procedures or laparoscopic procedures that utilize multiple incisions that are significant in size in relation to the patient size, single-port surgery may be advantageous in children. Initially used for appendectomies and cholecystectomies, more centers are starting to develop single-port techniques for adrenalectomy.[37–43] The single-port technique can be used for TA, PRA, or LRA and usually involves a single scope and two ports through a single access sheath in one incision. A case control study by Walz et al.[42] of a single-port retroperitoneal adrenalectomy versus a conventional retroperitoneal adrenalectomy found that the single-port technique had significantly shorter hospital stays with no differences in complication rates, but had higher open conversion rates and longer operative times.

OPEN ADRENALECTOMY

MIA in the pediatric population is continuously evolving. However, given the relative inexperience with MIA in children and the predominance of neuroblastomas, which may not be amenable to MIA, pediatric surgeons and urologists should be familiar with the various open approaches to adrenalectomy as well.

Flank Approach

The standard extrapleural, extraperitoneal flank approach to the adrenal gland may be performed for either left or right adrenalectomy. This technique offers the advantage of utilizing the positioning and initial exposure, similar to radical nephrectomies (Figure 18.4). For right adrenalectomy, the retroperitoneal space is first identified by medial reflection of the colon and duodenum. The liver is dissected off the anterior surface of the adrenal, allowing ligation of the superior vasculature to the gland. This dissection is facilitated by inferior traction on the kidney, and the mobilization is continued along the posterior abdominal wall and diaphragm from lateral to medial. The small arterial branches to the adrenal should be divided with hemoclips as they are encountered. The IVC is then exposed, and the adrenal vein identified, dissected free, and divided with clips or ties. The inferior attachments of the adrenal to the kidney are released last, allowing removal of the gland.

Mobilization for left adrenalectomy begins with division of the splenorenal ligament. Gerota's fascia can be swept medially, and the pancreas retracted superiorly and medially, exposing the adrenal. The superior attachments of the adrenal are released from lateral to medial, leading to the renal hilum. The adrenal vein is isolated at its entry to the renal vein, where it is divided. The inferior aspect of the gland is dissected off the upper pole of the left kidney, and the gland is then removed.

Thoracoabdominal Adrenalectomy

The main indication for a thoracoabdominal approach to the adrenal gland is to provide maximum exposure for large tumors, particularly on the right side, where the liver and vena cava can impede exposure. However, this technique may increase pulmonary complications, as the diaphragm is divided and the thoracic cavity entered.[44] The patient is positioned in approximately 45° flank, and the incision is made through either the eighth or ninth intercostal space (Figure 18.5). The intercostal muscles are encountered and divided, revealing the muscle fibers of the diaphragm, which are circumferentially divided. Adrenalectomy is then performed as described above for the flank approach. At the conclusion of the procedure, a thoracostomy tube is placed in the ipsilateral hemithorax, and the diaphragm is closed using interrupted silk sutures.

Posterior Adrenalectomy

Currently, we use the open posterior approach to adrenalectomy primarily for simultaneous bilateral adrenalectomy, as in patients with Cushing's disease.[44] Patients are placed in the prone position, and an oblique incision is made overlying the 11th or 12th rib (Figure 18.6). After subperiosteal rib resection, the diaphragm and pleura are mobilized superiorly to expose the retroperitoneal space. For left adrenalectomy, the splenorenal ligament is first released laterally, and dissection then proceeds along the superior aspect of the gland from

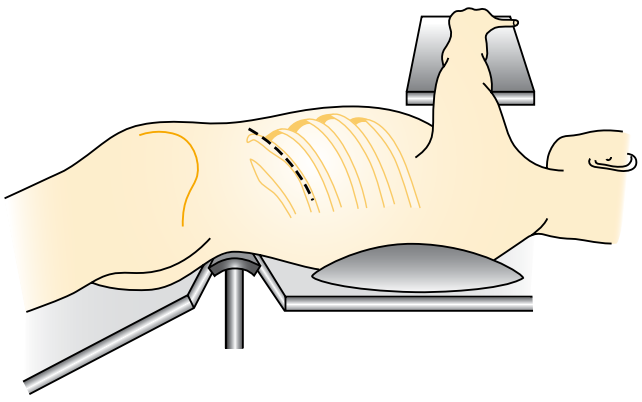

FIGURE 18.4 Positioning for flank approach to left adrenalectomy. The dotted line marks the 11th rib incision.

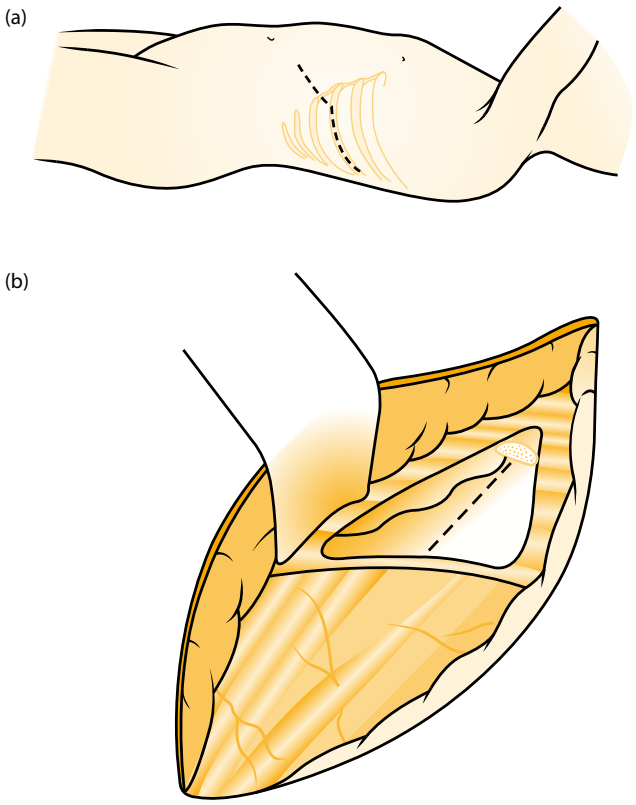

FIGURE 18.5 (a) Incision overlying the ninth rib for thoracoabdominal left adrenalectomy. (b) Exposure after resection of rib (seen cut at top of figure). The dotted line marks the incision in the diaphragm muscle.

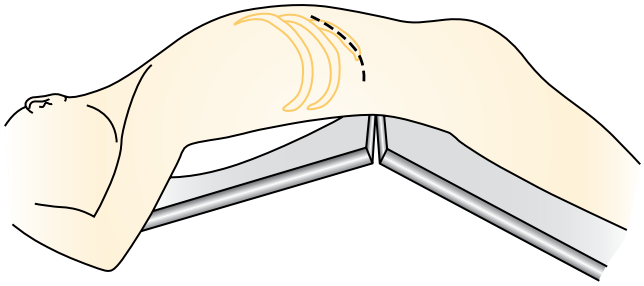

FIGURE 18.6 Positioning for (standard) posterior approach to adrenalectomy.

lateral to medial. This dissection may be facilitated by downward manual traction on the kidney. Medially, the left adrenal vein is identified and divided with clips or ties at its insertion into the left renal vein. Dissection is completed along the inferior aspect of the gland, and the adrenal is removed.

For a posterior right adrenalectomy, the liver is initially dissected off the adrenal and retracted cephalad. The superior vascular attachments of the gland are then divided from lateral to medial, until the vena cava is exposed. The lateral wall of the vena cava is dissected to the origin of the right adrenal vein, which can be clipped or tied and divided. After division of the vein, the inferior attachments of the gland are released, and the adrenal is removed. Given the often difficult exposure of the right adrenal vein through this (standard) posterior approach, we perform open right adrenalectomy via a modified posterior approach, where the patient's position on the operating table approximates that used during a Gil-Vernet dorsal lumbotomy incision (Figure 18.7).[45] An 11th or 12th rib incision is made, and the liver is mobilized as described above. However, as the vena cava is exposed by division of the superior attachments of the gland, the adrenal vein is encountered coursing toward the operating surgeon, thereby facilitating its identification and division. In the (standard) posterior approach, the vein lies in a posterior position and is thus at risk of avulsion during exposure.[46] The remainder of the dissection proceeds as for the standard posterior approach.

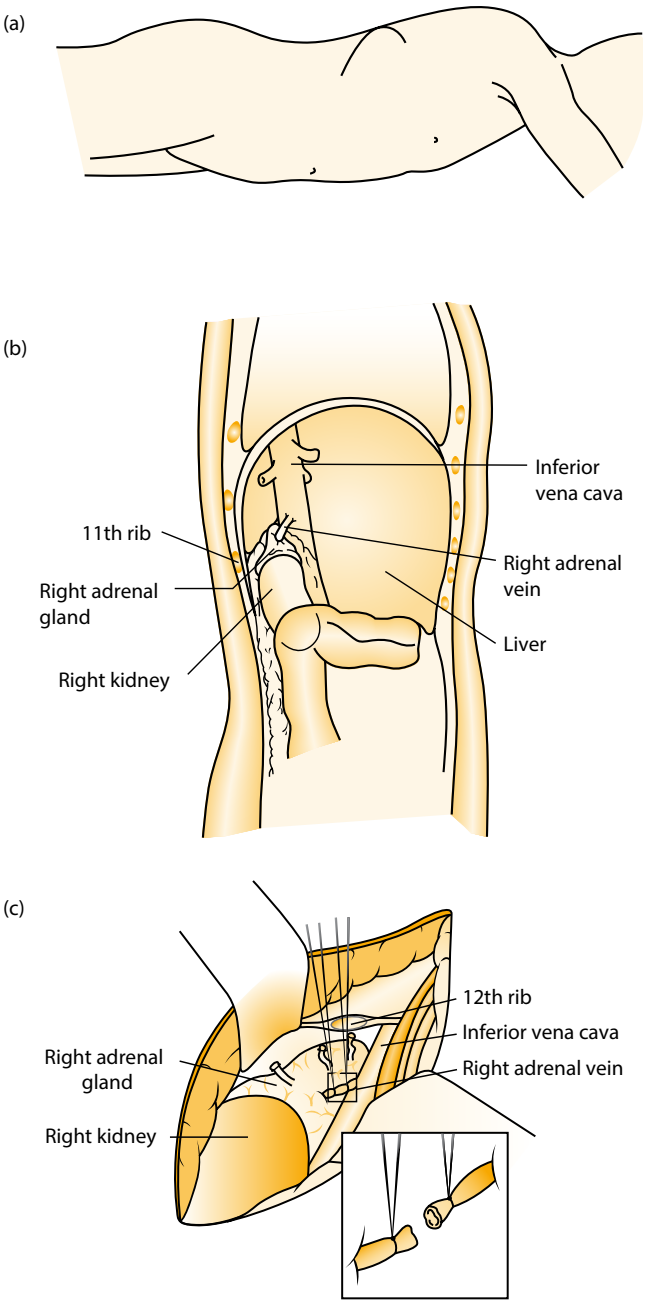

FIGURE 18.7 Modified posterior right adrenalectomy. (a) Positioning and incision. (b) View of adrenal bed, with right adrenal vein visible, seen during this approach. (c) Exposure and division of right adrenal vein.

Transabdominal Adrenalectomy

Transabdominal adrenalectomy is indicated primarily to facilitate complete abdominal exploration, as in the case of multiple pheochromocytomas, for patients with large adrenal carcinomas, and for adrenal lesions with involvement of the IVC. A chevron incision is used to gain access to the peritoneum, which is then systematically explored for lesions and metastases. Once this has been accomplished, right adrenalectomy may be performed by reflection of the hepatic flexure of the colon inferiorly and incision in the posterior peritoneum lateral to the kidney. This allows reflection of the liver superiorly and exposes the anterior vena cava, approximately at the level of the renal hilum. Cephalad dissection along the anterolateral wall of the vena cava leads to the right adrenal vein, which is then divided. The superior vasculature of the adrenal is released next, proceeding from the medial to the lateral aspects and facilitated by downward manual traction on the kidney. Lastly, the inferior attachments of the adrenal to the right kidney are mobilized.

For left adrenalectomy, the colon is first reflected medially, and the renal hilum identified and dissected. The left adrenal vein is divided as it enters the left renal vein. The anterior adrenal surface is then exposed by mobilization of the pancreas and spleen. The remainder of the dissection proceeds from the medial to the lateral aspect along the superior and inferior borders of the gland.

COMPLICATIONS OF ADRENAL SURGERY

Bleeding may be encountered during either OA or MIA. Anomalous vasculature may be present and, if not anticipated, may lead to significant bleeding. Castilho et al.[47] reported conversion of a laparoscopic procedure to open when an anomalous right adrenal vein was not recognized draining to the liver. When operating on the left adrenal, particular care should be taken to avoid injury to Belsey's artery, a communicating branch between the left gastric and inferior phrenic arteries. This vessel lies close to the esophageal hiatus, and is often accompanied by a phrenic vein.[48] When encountered, Belsey's artery, as well as any associated phrenic vessels, should be ligated to prevent avulsion.

Injury to adjacent organs may also occur during adrenalectomy, most commonly to the diaphragm and pleura. If recognized intraoperatively, the injury may be repaired without the need for thoracostomy tube placement. If such an injury occurs during OA, a red rubber catheter is placed through the defect, with the other end draining into a container of water. This defect is closed with a purse-string chromic suture during hyperinflation of the lung once no bubbles are seen exiting the water end of the catheter. The catheter is removed immediately prior to tightening the purse-string suture. Laparoscopic identification and suture repair of diaphragmatic injuries has also been reported.[49] In any case of diaphragmatic injury, a chest radiograph should be obtained postoperatively to evaluate for pneumothorax, and a thoracostomy tube may be placed at that time if necessary. Other adjacent organ injuries that may occur during adrenalectomy include capsular tears of the liver or spleen, which usually can be managed with a combination of manual tapenade, argon beam coagulation, and hemostatic gel packing.

Complications specific to the laparoscopic approach include trocar injury during placement and port site hernia. The passage of trocars should be done under direct vision; if inadvertent organ injury is suspected, close inspection and repair should be performed. Moreover, when exchanging instruments during the case, they should be passed under direct visual guidance. With regard to postoperative port site herniation, there is no consensus on the minimum port site size that necessitates closure; however, the need for closure of smaller port sites depends on both the size of the child and the type of trocar used.

SPECIAL CONSIDERATIONS

Neuroblastoma

Neuroblastoma is the most common extracranial solid tumor in children, with 1 case per 7000 live births. The adrenal gland is the origin of the tumor in 40% of the cases, which explains why neuroblastoma is a major cause of adrenalectomy in children.[15,50] The growth pattern of neuroblastoma can be variable, ranging from sharply demarcated tumors to highly infiltrative lesions. Likewise, the role of surgery in the management of neuroblastoma varies. Low-risk neuroblastoma may be eligible for surveillance, whereas localized tumors with favorable biologic factors can be cured with surgical resection. In advanced disease, resection is only one component of multimodal therapy. The often infiltrative growth pattern of neuroblastoma has led most surgeons to excise these tumors via open resection, with the choice of a transabdominal versus retroperitoneal approach guided by tumor location and adjacent organ involvement.

The role of MIA in neuroblastoma has been evolving over the past 15–20 years. In two large multicenter studies of pediatric neuroblastoma, Iwanaka et al.[16] and Leclair et al.[15] found that MIAs should be mainly performed in children with encapsulated masses and low-risk neuroblastomas, such as in young patients found with adrenal masses prenatally or in mass screening efforts. In a comparison of laparoscopic adrenalectomy with OA for pediatric adrenal neuroblastoma, Kelleher et al.[51] found that laparoscopic adrenalectomy could be safely performed with equivalent outcomes in patients with tumors smaller than 5 cm and without vascular encasement. Recent advances in technology and understanding of the disease have allowed for better assessments of tumor biology and risk stratification. The International Neuroblastoma Risk Group Task Force[52] developed a new staging system based on clinical criteria and IDRFs. Masses with IDRFs include masses that surround major vessels or nerves or invading structures, such as the spinal canal. Tumor histology and biology are also essential for risk stratification, including the presence of MYCN amplification, ploidy, and genomics.

In localized neuroblastoma without IDRFs (stage L1), the masses are suitable for primary resection with MIA as a feasible option if the tumor is well encapsulated. In neuroblastoma with IDRFs (stage L2), a biopsy of the mass gives information about the biology of the tumor. Patients with L2 neuroblastoma undergo neoadjuvant chemotherapy, and should then be reassessed after the chemotherapy. If all the surgical risk factors are negative (which includes having all the major vessels free of disease), and if the histologic features of the tumor are favorable, MIA may be safely utilized for treatment. Monclair et al.[53] have further shown that a select group of L2 patients with few IDRFs may safely undergo primary surgery with excellent overall survival. Regardless of the technique, it is essential to have a complete resection, as any remnant increases the risk of local recurrence.

The influence of local control by surgery or radiation therapy on overall survival in metastatic neuroblastoma (stage M) is controversial.[54] Englum et al.[55] have shown that in a cohort of children with high-risk neuroblastoma, the majority of whom had metastatic disease, resection of greater than 90% of the tumor was associated with improved overall survival. Children in complete remission or good partial remission of metastases after chemotherapy may benefit from local control. In children with metastatic neuroblastoma and no IDRFs, MIA may allow for a rapid postoperative recovery and immediate resumption of medical therapy, thereby minimizing the interruption of chemotherapy.

Pheochromocytoma

Pheochromocytomas are catecholamine-secreting tumors from the adrenal medulla. Approximately 10% of cases of pheochromocytoma occur in children, and 40% of pediatric patients with pheochromocytoma are associated with known genetic mutations.[56,57] Pheochromocytomas are characterized by catecholamine production; as such, the clinical manifestations of these tumors result from the physiologic effects of catecholamine excess.

Close cooperation of the pediatric urology, medicine, and anesthesiology teams is required in the management of patients with a pheochromocytoma. Patients are typically treated preoperatively with alpha-blockade (phenoxybenzamine) to control their blood pressure. Beta-blockers may be added to alpha-blockers to prevent arrhythmias, but beta-blockade administered without prior alpha-blockade may cause a significant increase in peripheral vascular resistance due to unopposed alpha-activity.[46] In addition, many patients have decreased intravascular volume, and therefore intravenous fluids are aggressively administered in the perioperative period to expand plasma volume and minimize intraoperative and postoperative hypotension. Severe intraoperative hemodynamic instability from catecholamine release may occur if the adrenal is manipulated. Early control and division of the main adrenal vein is essential in order to prevent the systemic release of catecholamines during dissection of the gland. Given the potential for blood pressure fluctuation, which may occur after ligation of the adrenal vein, the anesthesiologist should be notified at the time of adrenal vein division, and should be prepared to give intravenous fluids and vasopressors if needed.

Hereditary pheochromocytomas occur in von Hippel–Lindau (VHL) syndrome, multiple endocrine neoplasia (MEN) type 2, familial paraganglioma syndromes (succinate dehydrogenase gene mutations), and neurofibromatosis type 1. Hereditary pheochromocytomas, especially those with a mutation in succinate dehydrogenase B (SDHB), are often malignant and bilateral. MIA has been successfully used as the main treatment of choice for pheochromocytomas. The approach (TA, LRA, or PRA) depends on the size of the mass and experience of the surgical team. Two-thirds of children with an SDHB mutation have malignant tumors, so a total adrenalectomy is the best option. In VHL and MEN type 2, the risk of malignancy is low, so a partial adrenalectomy can be a viable alternative to prevent lifelong glucocorticoid and mineralocorticoid replacements and decrease the risk of metachronous tumor.[58] Volkin et al.[59] and Fallon et al.[60] have reported successful partial adrenalectomy in pediatric patients with VHL and pheochromocytomas via both open and minimally invasive approaches, with utilization of intraoperative ultrasound in minimally invasive cases. In adult patients with VHL, the recurrence rate was found to be close to 11%, with preservation of adrenal function in 90%.[58] For a partial adrenalectomy, the tumor pseudocapsule is identified, and the plane between the mass and normal adrenal gland is dissected out.

Congenital Adrenal Hyperplasia

Hugh Hampton Young first reported adrenalectomy as a treatment for congenital adrenal hyperplasia (CAH) in the 1930s.[61] With the development of synthetic adrenal steroids, however, the management of these patients has become almost exclusively medical (apart from genital reconstructive surgery). For most patients, the dosage of exogenous steroids needed to impede adrenal androgen production does not result in severe hypercortisolism with its associated sequelae. However, in some patients, suppression of adrenocorticotropic hormone (ACTH) is difficult, requiring large doses of exogenous steroids, which may cause obesity, hirsutism, acne, and other cushingoid features. In women, hypercortisolism may also result in menstrual irregularities, significant bone loss, and infertility.[62]

Van Wyk and Ritzen revisited the concept of adrenalectomy as a treatment for CAH patients who were difficult to manage on medical therapy.[63] In a study of 18 patients who underwent bilateral adrenalectomy for treatment of CAH and were followed an average of 59 months, virtually all patients had a significant decrease in androgen excess.[64] A separate investigation reported two women with CAH who had been infertile and oligomenorrheic who then experienced successful pregnancies following bilateral adrenalectomy.[65] Castillo et al.[66] reported a series of three patients with failure to respond to medical therapy who achieved either complete or partial regression of acne, hyperpigmentation, and virilization symptoms after bilateral MIA. In addition, although the majority of studies on adrenalectomy as a treatment for CAH have involved patients with 21-hydroxylase deficiency, patients with 11-beta-hydroxylase deficiency, who are prone to develop hypertension as part of the disease process, have also been treated with bilateral adrenalectomy, with a subsequent improvement in blood pressure.[63]

Lastly, whereas the aforementioned studies employed adrenalectomy as a treatment for CAH patients, the role of prophylactic adrenalectomy has been explored for patients with CAH as well.[62] Until longer-term data are available, however, prophylactic adrenalectomy is still considered experimental.

CHAPTER 19

Basic Science of the Kidney

Heidi A. Stephany, John C. Thomas, and John C. Pope IV

INTRODUCTION

An attempt to define the term *translational* compared to deciphering a foreign language in that "getting the word right is relatively easy but getting the meaning of the word is much more difficult."[1] The process of translating basic science research to improvements in clinical patient care has revolutionized the way medicine is practiced in the late twentieth century and early twenty-first century. One example is in the area of renal transplantation. While the refinement of surgical technique has contributed to the overall success of the transplant, one must also recognize the monumental advances in immunobiology that have ultimately determined the long-term outcome of the allograft. These translational efforts have led to the development of immunosuppressive drugs capable of preventing allograft rejection in the patient. Just as this type of research has contributed to the success of renal transplantation, pediatric urologists and nephrologists are faced with the issue of finding ways to prevent certain anomalies in their patients that ultimately lead to renal failure and the need for transplantation.

In order to address this issue, clinicians must first have a general understanding of normal and abnormal molecular renal development. Second, while urinary obstruction, untreated neurogenic bladders, and vesicoureteral reflux (VUR) are just a few known disease processes that can lead to progressive renal damage, current research is focusing on ways to detect at-risk individuals in whom early intervention is beneficial. Understanding the pathophysiology of nephropathy at the cellular level can provide potential markers that could possibly alert the caregiver to a particular problem before renal damage occurs (Figure 19.1). Unfortunately, despite our best efforts, some children will continue to develop renal failure, necessitating renal replacement therapy, and better alternatives, such as tissue engineering of new organs, are actively being pursued.

This chapter briefly reviews the developmental biology of the kidney to highlight some of the more important regulatory factors involved in nephrogenesis. The pathophysiology of congenital obstructive nephropathy is used as an example to illustrate one congenital anomaly, particularly common in the urologic arena, whose ultimate aberrant molecular events can lead to end-stage renal disease. More importantly, it focuses on recent laboratory efforts that have elucidated numerous potential markers at the cellular level that play a role in the process of renal deterioration following insult to the developing kidney. Theoretic therapeutic options that act to inhibit or slow these damaging mechanisms, as well as potential alternatives to present renal replacement therapy, namely, tissue engineering and stem cell research, are also reviewed. Finally, a review of renal physiology is outlined, highlighting key factors relevant to the urologist.

Molecular Development of the Kidney

As the embryology of the kidney is addressed in Chapter 20, this section focuses on the numerous molecular signals that result in normal renal development. Formation of the kidney is a culmination of reciprocal inductive signals that occur between the ureteral bud and metanephric blastema. The bud develops from the Wolffian duct, and the mesonephric mesenchyme arises from intermediate mesoderm located in the caudal portion of the nephrogenic cord. Once these structures interact, the nephrons develop from mesenchymal transformation and the collecting system is formed from ureteral bud outgrowth and subsequent branching.

Since 2009, there have been more than 2900 genes implicated in genitourinary tract development, and they are cataloged in the Genitourinary Development Molecular Anatomy Project database (http://www.GUDMAP.org).[2,3] The goal of this project was to recognize molecular markers for the development of reporter mouse strains to further elucidate renal development.[4] Many of the major events in early renal development are controlled by highly conserved genes that regulate eye development in *Drosphila*.[5] The use of transgenic mice has generated much data concerning nephrogenesis, as manipulation of a specific gene can result in phenotypes consistent with human congenital anomalies of the kidney and urinary tract (CAKUT). Mesenchymal–epithelial transition (MET) is crucial for early renal development, as the pronephros becomes the definitive metanephros. One of the most important regulators of this early step is a transcription factor known as *PAX-2*. Mice homozygous for the *PAX-2* null mutation lack ureters, kidneys, and genital tracts, whereas heterozygous mice often form hypoplastic kidneys.[6] Also, these animals lack expression of *c-RET*, an important tyrosine kinase receptor expressed on the tips of the ureteral bud.[6,7] The *c-RET* receptor binds glial cell line–derived neurotrophic factor (GDNF), which is secreted from the developing mesenchyme. Ureteral buds in mice lacking *c-RET* expression fail to branch, whereas loss of GDNF results in apoptosis of the metanephric mesenchyme, both events

leading to renal agenesis.[8,9] A similar phenotype is seen with mutations of upstream regulation of GDNF, namely, additional transcription factors, including *PAX-2*, *EYA-1*, and *WT-1*.[10,11] Mice lacking *EYA-1* or (*eyes absent*) lack expression of GDNF, whereas mutation of *WT-1*, which is expressed by uninduced mesenchyme, results in reduced expression of GDNF, although not enough to prevent renal agenesis.[8,10]

MET within the mesonephric mesenchyme occurs only following proper inductive signals from the invading ureteric bud. Once induction occurs, metanephric mesenchyme condenses at the tips of the branching bud to form mesenchymal aggregates. These aggregates epithelialize and begin the transformation from the vesicle stage, comma stage, and S-stage to ultimate fusion with the collecting duct, forming mature nephrons.[10] As condensation occurs, these cells express *WNT4*, an important glycoprotein exclusively found in kidney mesenchymal cells, which promotes MET through an autocrine activation mechanism. Nephrons in mice lacking *WNT4* fail to epithelialize.[12,13] Nephron maturation is also regulated by *BMP7*, a growth factor that is part of the transforming growth factor β (TGFβ) superfamily of signaling molecules. *BMP7* appears to operate downstream of other factors, like *WT-1*, *PAX-2*, *HNF1B*, and *WNT4*, and like *PAX-2*, it is expressed by both the mesenchyme and ureteral bud.[7] Homozygous mice with a mutation of *BMP7* have dysplastic kidneys that appear arrested in development and failure of mesenchymal induction, suggesting that *BMP7* may be a survival factor.[7,14] As mentioned, the TGFβ superfamily plays a role in kidney development, with *Gdf11* and *BMP4* necessary for outgrowth of the ureteric bud. One of the primary mediators of TGFβ signaling is *SMAD4*, and while collecting duct development is independent of *SMAD4*, removal of *SMAD4* causes impairment in the recruitment and organization of nephrogenic mesenchyme.[15] Further evidence supporting the importance of *SMAD4* has been demonstrated by the absence of canonical *SMAD4* signaling in ureteral mesenchyme leads to urothelial disorganization. *SMAD4* deficiency reduces the number and contractility of ureteral smooth muscle cells, and thus leads to a functional ureteropelvic junction obstruction (UPJO) secondary to abnormal peristalsis.[16]

Apoptosis plays a major role in the kidney, achieving its characteristic reniform shape. As certain areas of the undifferentiated mesenchyme (UMC) are destined to become crucial parts of the kidney, other cells undergo apoptosis. The renin–angiotensin system (RAS) plays a role in this process, mainly through the upregulation of the angiotensin types 1 and 2 (AT1 and AT2) receptors. The ligand for these receptors is angiotensin II, formed from the cleavage of angiotensin I by angiotensin-converting enzyme (ACE). Although AT1 receptors modulate renal vascular development and are found in more differentiated tissues of the kidney, AT2 receptors are expressed by UMC.[17] Mice with a null mutation of the AT2 receptor display phenotypes similar to those of human CAKUT, including VUR, UPJO, and duplicated collecting systems.[18,19] In vitro and in vivo studies show that angiotensin II promotes apoptosis of the UMC surrounding the developing urinary tract.[20] These studies suggest that mutations in AT2 can lead to untimely apoptosis of the UMC, potentially hindering not only the growth of the bud toward the mesenchyme, but also the diffusion of signals between these structures. Thus, the bud may develop from an ectopic location from the Wolffian duct and lead to VUR or renal hypo- or dysplasia.[21] Additional studies have demonstrated the importance of the interaction between the RAS and *c-RET*. Angiotensin II induces *c-RET* signaling and thus promotes ureteric bud branching.[22] Numerous other factors and genes are involved in renal development; however, this is beyond the scope of this section of the chapter. Table 19.1 shows other important genes involved in nephrogenesis. Some of the aforementioned genes, as well as others, are involved in more common syndromes seen clinically, which are listed in Table 19.2.[23]

TABLE 19.1 Genes involved in kidney development and the defect caused in mice lacking expression of the involved gene

Gene	Function	Homozygous loss in mice (–/–)[b]
WT-1[a]	Presence necessary for ureteral bud formation, precedes PAX2 and WNT-4 expression	Renal agenesis, absent ureteral bud formation
PAX-2[a]	Mesenchymal–epithelial conversion, expressed in ureteral bud, so probably has role	*PAX-2*$^{-/-}$ equals renal agenesis, absent ureteral bud formation; *PAX-2*$^{+/-}$ equals renal hypoplasia
WNT-4[a]	Morphogenesis of pretubular and tubular structures; mesenchymal–epithelial conversion	Small dysplastic kidneys
GDNF[a]	Ureteral bud formation; branching	Renal agenesis, absent ureteral bud formation
RET[a]	Receptor for GDNF-GDNFR-α complex, ureteral bud formation, and branching	Renal agenesis or tiny dysplastic kidneys
APC	Its protein product destabilizes β-catenin	In humans, mutations cause colon cancer
AT-1	Maturation of glomerular vessels, formation of renal pelvis	Absent renal pelves, immature glomeruli
AT-2	Mesenchymal cell apoptotic agent, has role in ureteral bud development	Congenital anomalies of kidneys and urinary tract
BCL-2	Prevents pre-epithelial, epithelial cell apoptosis	Renal agenesis, widespread apoptosis
BF-2	Present in mesenchymal cells that become stromal cells, persists in stromal cells, ureteral elongation, epithelial cell polarity	Short ureter, hypoplastic kidneys, incomplete rotation, renal fusion
BMP-4	Inhibits *WNT-11* activity, prevents ectopic ureteral bud formation, lengthens stalk of branches	*BMP-4*$^{-/-}$ equals congenital anomalies of kidneys and urinary tract
BMP-7	Prevents pre-epithelial cell apoptosis	Renal dysplasia
EMX-2	Ureteral bud branching, possible ureteral bud inducer of metanephric *WNT-4* expression, prevents pre-epithelial cell apoptosis	Renal agenesis, ureteral bud degeneration
EYA-1	May be inducer of GDNF expression and up-regulator of BCL-2	Renal agenesis, absent ureteral bud formation
FGF-2	Possible role in ureteral bud induction of mesenchymal–epithelial transformation	No published examples found
GDNFR-α	Auxillary receptor GDNF-α, ureteral bud formation; branching	Renal agenesis
IGF-II	Its protein product inhibits mesenchymal cell apoptosis	No published examples found
KAL-1	Specific role not known	In humans, mutation is associated with unilateral, bilateral renal agenesis
Ld	Ureteral bud formation	Renal agenesis or dysplasia, absent ureteral bud formation or penetration
LIF-1	Activates STAT-3, possible requirement for epithelial tubulogenesis, may stimulate *WNT-4* expression	No published examples found
LIM-1	Not known but likely has role in mesenchymal–epithelial conversion	Some have bilateral renal agenesis
PDGF-β	Mesangial cell formation	Absent mesangial cells
PKD-1	Protein product is polycystin-1, tubule morphogenesis, participates in cell-to-cell, and cell-to-extracellular adhesion bonds	Autosomal dominant polycystic kidney disease
PKD-2	Protein product is polycystin-2, translocates polycystin-1 to cell membrane	No published examples found
RAR	Likely inducer of Hox activity	Renal agenesis or dysplasia
SHH	May have role in ureteral bud induction of metanephric development	Hypoplastic kidneys, defective branching
VHL	Strengthens destabilizing bonds of glycogen synthase kinase-3, adenosine polyposis coli with β-catenin	In humans, mutation causes von Hippel-Lindau disease
WNT-11	Ureteral bud branching	No defects

[a] These genes may be focused on, but relative perceived importance of genes may change with time. Other genes are listed in alphabetical order. Some genes are not included in list and others have not yet been identified.

[b] Significance of each gene implied by the major defect that its absence causes.

Congenital Obstructive Nephropathy

Congenital obstructive nephropathy is but one of many developmental aberrations that occur in the kidney or urinary tract that can lead to renal injury and potentially renal failure. Ideally, the embryologic process of urinary tract development could ultimately be controlled so that these anomalies do not occur. Short of accomplishing this feat, it is critical to know which patients are at risk for renal injury and/or failure. If these patients could be

TABLE 19.2 Genetic disorders for human congenital anomalies of the kidney and urinary tract (CAKUT)

Gene (chromosome)	Gene product/function	Clinical syndrome	Phenotypes/symptom
PAX-2 (10q24–25)	Transcription factor	Renal–coloboma syndrome	Renal hypoplasia, solitary kidney, vesicoureteric reflux, optic nerve colobomas hearing loss
KAL (Xp22.3)	Anosmin1 protein functioning in neuronal migration and axonal targeting	Kallmann syndrome	Hypogonadotropic hypogonadism, anosmia, pes cavus, mirror movements of the hands, high arched palate, carebellar ataxia, renal agenesis/aplasia. Potter sequence. duplex systems, vesicoureteric reflux, lack of the vas deferens
EYA-1 (8q13.3)	Organogenesis	Branchio-oto-renal syndrome	Branchial cysts or fistulae, external ear malformation, preauricular pits, hearing loss cataracts, ocular anterior segment anomalies, unilateral renal agenesis with contralateral hypodysplasia, bilateral hypodysplasia, bilateral renal agenesis, ureteropelvic junction obstruction, vesicoureteral reflux, bifid kidneys
AGTR2 (Xq22–23)	Angiotensin II receptor type 2		Common CAKUT
HNF-1β (17cen-q21.3)	Hepatocyte nuclear factor-1β, organogenesis	Maturity-onset diabetes of the young	Young-onset non-insulin-dependent diabetes mellitus, renal cysts, hypoplastic glomerulocystic kidney disease, cystic renal dysplasia, solitary kidney, Mullerian anomalies

Source: Reproduced with permission from Nakanishi K, Yoshikawa N. *Pediatr Int* 2003;45:610–6.

identified early, it would theoretically be possible to slow or altogether prevent this deterioration in renal function.

Currently, there is significant controversy regarding the management of individuals with significant hydronephrosis based on the fact that hydronephrosis is not synonymous with obstruction.[24] Both nonoperative and early operative approaches have been advocated for infants with severe unilateral hydronephrosis.[25,26] Based on a more thorough understanding of the pathophysiology of renal fibrosis, the potential use of "biomarkers" may help to lessen this controversy. Biomarkers are defined as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathological processes, or pharmacologic responses to a therapeutic intervention."[27] Biomarkers for congenital obstructive nephropathy include anatomic details of the kidney gained through the use of imaging techniques, radionuclide scans to determine renal function, and microscopic analysis of biopsy specimens following obstruction.[27] The challenge faced by clinicians is learning how to use the information gained from these markers to direct appropriate care, such as timing of surgical intervention and medical treatment (i.e., administration of ACE inhibitors). The identification of biomarkers has been a popular area of research recently, and investigators have studied many urinary markers. One particular study examined the role of urinary epidermal growth factor (EGF), monocyte chemotactic protein-1, and β2-microglobulin, and found a significant correlation with tubulointerstitial damage in humans undergoing UPJO repair.[28] Urinary kidney injury molecule-1 and neutrophil gelatinase-associated lipocain have also been identified, and increasing levels are associated with worsening obstruction.[29] The ultimate goal for biomarkers in the pediatric urology arena is to recognize those patients at greatest risk for renal damage and providing appropriate intervention in a time-dependent manner to preserve and maintain renal function. While multiple studies have looked at potential biomarkers, the clinical application of various markers is still disputed.

Inconsistencies in the completion of nephrogenesis in various animal models have made it difficult to correlate postobstructive findings with those that occur in human obstructive nephropathy. Despite this shortcoming, animal models have contributed greatly to our understanding of fetal renal disease. These models consist of animals with spontaneous mutations or gene deletions (knockout), resulting in the desired phenotype, as well as surgically induced models of renal obstruction.[30] There is a broad spectrum of severity of obstruction in the human, and occult renal damage at the cellular level likely occurs prior to the development of hydronephrosis. Perhaps the most accurate model to demonstrate this is the neonatal rat, as only 10% of its nephrons are formed at birth, while the rest develop during the first week of life.[31] Thornhill et al. subjected the neonatal rat to partial unilateral ureteral obstruction (UUO).[32] In this study, renal growth decreased by 60% with a 70%–75% reduction in ureteral lumen, but much less when the lumen was reduced by ≤65%. Also, tubular atrophy and interstitial fibrosis correlated with tubular apoptosis and developed prior to renal pelvic dilation. Finally, persistent moderate partial UUO led to a marked decrease in ipsilateral glomerular filtration rate (GFR) and proteinuria before impairment of renal growth.[32] These findings carry extremely important clinical implications, as currently, no diagnostic test exists that allows one to reliably predict whether a hydronephrotic kidney is at risk for progressive renal injury at the cellular level.

Following the tireless efforts of numerous investigators, we now have a better understanding of normal renal development and the genes involved, along with the different mechanisms of renal damage following obstruction. Normal nephrogenesis includes increasing the number of nephrons and maturation of the renal vasculature,

glomeruli, tubules, and interstitium. This complex process involves the RAS and a balance between cellular proliferation and programmed cell death (apoptosis).[33,34] Significant obstruction can lead to impaired renal growth, resulting from tubular dilation and apoptosis, tubular atrophy, inflammatory infiltration of the interstitium, and unchecked accumulation of the extracellular matrix (ECM), all culminating in renal fibrosis and glomerulosclerosis.[27,35,36]

The following section outlines important mediators in fibrotic renal disease by briefly discussing their actions at the cellular level. Since other conditions seen clinically in pediatric urology can also result in renal fibrosis, these mediators can potentially be used as prognostic indicators of renal damage and be universally applied to multiple disease processes. Finally, once the role of these markers is understood, potential therapeutic options based on the activation or inhibition of their actions will be discussed.

TGFβ1

As mentioned, the TGFβ family is involved in many aspects of renal development and growth, but also has been implicated in fibrosis, particularly TGFβ1, which is a regulatory cytokine that is upregulated in response to tissue injury and can act synergistically with other growth factors to either inhibit or stimulate ECM deposition by recruiting fibroblasts.[37] Overaccumulation of ECM proteins, including fibronectin, collagen, and proteoglycans, as well as blocking matrix degradation by stimulating the action of protease inhibitors, results in fibrosis.[37–39] Tissue and urinary TGFβ1 has been shown to be increased in both animal and human models following urinary tract obstruction.[40–42] TGFβ exists as three isoforms (TGFβ1, TGFβ2, and TGFβ3), all capable of inducing fibrogenic effects on the obstructed kidney.[43] The main isoform is TGFβ1, and using immunohistochemistry in kidneys subjected to UUO, this cytokine has been localized to the renal tubules in the cortex and outer medulla, as well as from infiltrating macrophages in the interstitium.[44]

The complexity of TGFβ signaling is beyond the scope of this chapter, but initially, TGFβ binds the Type II serine/threonine kinase receptor, which then recruits and phosphorylates the Type I receptor, resulting in its activation. This receptor complex can then activate multiple signaling pathways, including RhoA, p38 mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3K), and the *SMAD* pathway.[45–48] Downstream phosphorylation of *SMAD2* results in the nuclear translocation of *SMAD2*, *3*, and *4* protein complexes.[49,50] *SMAD3* has been implicated in the fibrotic process through the activation of collagen promoters, downregulation of matrix-degrading enzymes, and upregulation of matrix metalloproteinase (MMP) inhibitors.[50,51] TGFβ1 also modulates the expression of microRNAs; in particular, it reduces the expression of mi-R-29, thus further promoting ECM deposition[52] In addition, TGFβ1 also drives epithelial–mesenchymal transition (EMT), which is characterized by tubular epithelial cell migration into the interstitium, where they are transformed into mesenchymal, myofibroblast-type cells. Renal tubular cells express fibroblast-specific protein-1 (FSP-1), which can be induced by TGFβ1 released by infiltrating macrophages or fibroblasts during renal injury. This activation allows certain epithelial cells to acquire mesenchymal migratory capacity and escape into the interstitium, where they facilitate deposition of interstitial ECM.[53–55] Recently, the role of EMT in fibrosis has been investigated, particularly looking at MMP-2. In MMP-2 knockout mice, less fibrosis was evident and there was a decreased amount of TGFβ and other EMT-related molecules, further suggesting the importance of EMT in progressive fibrosis in renal injury.[56]

TGFβ1 and its signaling pathways are major contributors to renal fibrosis following renal injury, and any of the numerous factors involved have the potential to serve as important biomarkers and therapeutic targets for subclinical renal injury following obstruction. If patients at risk for progressive renal fibrosis can be identified, then hopefully intervention can take place to slow, stop, or potentially reverse the fibrotic process. The significant advances in the laboratory deciphering all the many roles of TGFβ and downstream targets in fibrosis are daunting, yet numerous advances continue to promote further research.

Renin–Angiotensin System

In addition to TGFβ1, the RAS has also been implicated in the pathophysiology of renal fibrosis following obstruction. Along with regulation of renal growth, investigators have shown that the RAS plays a major role in the early response of a neonatal kidney following obstruction, and that reduced growth was secondary to decreased cellular proliferation and increased apoptosis.[57,58] Consistent with this early activation of the RAS in the neonatal kidney, there is a prompt and marked increase in ipsilateral renin mRNA following unilateral UUO with contralateral suppression of renin in the neonatal rat compared with adult rats. The persistence of an immature microvascular renin distribution, the presence of α-smooth muscle actin (α-SMA) in the peritubular capillaries, and the decreased total DNA content in the obstructed neonatal kidney all confirm the deleterious effects of obstruction in the developing kidney.[59,60] Angiotensin II directly increases the production of TGFβ and can induce fibrosis via a TGFβ-dependent or independent mechanism through direct activation of plasminogen activator inhibitor-1 (PAI-1).[61–69] PAI-1 promotes fibrosis by preventing the breakdown of plasminogen to plasmin.[63]

In vitro studies of oxidative stress on rat proximal tubular cells illustrate the role of angiotensin II in the promotion of cellular apoptosis. This is primarily mediated via the induction of TGFβ and generation of reactive oxygen species (ROS).[70] The RAS promotes normal renal development, but in cases of obstructive uropathy, it can promote fibrosis and accentuate renal injury through a variety of mechanisms. Consequently, therapies directed at inhibition of the RAS carry much promise in attenuating renal damage secondary to urinary tract obstruction.

Apoptosis

Following chronic ureteral obstruction, tubular and interstitial cells undergo programmed cell death, or apoptosis, all of which lead to renal tissue loss.[71–73] Once the inductive signal for apoptosis occurs, this leads to the recruitment

and activation of cytosolic enzymes called caspases (cysteinyl aspartate-specific proteinases). Using a mouse model of UUO, investigators showed a progressive increase in the activation of these caspases, namely, caspase-3, compared with sham-operated animals.[72] Apoptosis of both tubular and interstitial cells paralleled this increase in caspase expression.

Many signals, including growth factors, cytokines, ROS, and angiotensin II, can all initiate apoptosis. A neutralizing antibody to TGFβ ameliorated tubular apoptosis following UUO in the rat, while administration of enalapril, an ACE inhibitor, provided partial protection against tubular cell apoptosis.[74] Nuclear factor-κB (NF-κB) is an inducible transcription factor that upon translocation to the nucleus can induce the transcription of various genes, including *BCL-2* family members, angiotensinogen, and pro-inflammatory mediators, including tumor necrosis factor α (TNFα).[75] Angiotensin II and TNFα can stimulate further activation of NF-κB, reinforcing a positive feedback loop.[39] Increased vascular resistance following UUO causes transient ischemia and increased release of angiotensin II. Once obstruction is relieved, ischemia–reperfusion injury may result secondary to increased release of ROS, such as hydrogen peroxide (H_2O_2). Following UUO in mice lacking catalase, an enzyme capable of neutralizing H_2O_2, there was an increase in tubular epithelial cell apoptosis and interstitial fibrosis compared with wild-type mice.[76,77] Recent evidence has also examined the role of Paired box 2 (PAX2) in UUO and apoptosis. Compared with sham mice, TGFβ1, PAX2, collagen IV, and caspase-3 were all increased in the obstructed model, and the authors concluded that PAX2 is a potential therapeutic target in the prevention of renal fibrosis.[78]

Finally, evidence has linked nitric oxide (NO) as a possible protector against apoptosis. NO is produced by inducible nitric oxide synthase (iNOS), which is spontaneously expressed in the kidney. Using knockout mice lacking iNOS, investigators showed increased tubular cell apoptosis.[79] From a clinical standpoint, iNOS activity has also been shown to be elevated in children with UPJO, presumably induced by inflammatory cytokines, including TNFα and monocyte chemoattractant protein-1 (MCP-1), the latter also found in the urine of children with UPJO.[80,81] Further studies are needed, however, to evaluate NO as a prognostic indicator of recoverability of renal function following urinary obstruction.[79] One study looked at augmenting nitric oxide and suggested that decreasing iNOS activity contributes to decreased renal function in UUO, and animals transfected with the iNOS gene demonstrated improved renal function after obstruction.[82] With all the advancements made in the laboratory arena, investigators are hoping to find not only therapeutic interventions, but also biomarkers to decrease the invasive measures currently used to follow patients with potential for ensuing renal fibrosis or failure.[83,84]

The above were meant to highlight different signals and processes involved in progressive renal damage following obstruction. By no means is this an exhaustive description, as many other mechanisms have been implicated. Although presented separately, it is important to remember that these occur simultaneously, and that induction of one process may be dependent on another. This may have a therapeutic benefit, as inhibiting one signal or process can have the advantageous and additive effect of attenuating another.

Treatment Options

Renal fibrosis and atrophy secondary to various diseases are complex processes that have become more understandable in the last 15 years through the work of numerous investigators. Defining and detecting this process earlier may allow us to manipulate and possibly prevent renal damage by inhibiting a specific growth factor or cytokine, or blocking an entire pathway by interfering with upstream or downstream mediators.[85,86] As previously discussed, TGFβ plays a major role in renal fibrosis following obstruction. Potential treatment options include TGFβ neutralizing antibodies, antisense oligonucleotides, and blockade with a naturally occurring proteoglycan called decorin, all of which have limited ECM accumulation in vivo and in vitro.[74,87–89] Targeting the RAS with ACE inhibition and AT1 blockade results in impaired fibroblast proliferation, decreased myofibroblastic differentiation, and lowering of both TGFβ levels and NF-κB isotype activation. Of note, ACE inhibition also attenuated monocyte and macrophage infiltration.[90,91] Use of a direct renin inhibitor, approved by the Food and Drug Administration (FDA) in 2007, was also evaluated in unilateral obstruction and had anti-inflammatory and antifibrotic effects, despite an increase in renin expression, which was postulated to have suppressed receptor expression via negative feedback.[92,93] NF-κB is responsible for the upregulation of various cytokines, inflammatory mediators, and cell adhesion molecules, such as ICAM-1. Inhibition of NF-κB in rat kidneys subjected to UUO using an activation inhibitor called dehydroxymethylepoxyquinomicin (DHMEQ) showed less interstitial fibrosis and volume than obstructed controls.[94] *SMAD3*–deficient mice undergoing UUO showed decreased scar formation, less α-SMA staining in the interstitial fibroblasts, and decreased deposition of both collagen I and III.[95] Using a nephrotoxic nephritis model in the rat, treatment with a pan-caspase inhibitor decreased apoptosis, tubulointerstitial inflammation, and mRNA levels of collagen I, III, and IV.[96] Finally, because the role of MCP-1 has been firmly established as a pro-fibrotic modulator, blocking its receptor CCR2 also decreased fibrosis following UUO in a mouse model.[97]

EGF is also an important peptide whose manipulation has potential therapeutic ramifications following UUO.[98] EGF is produced by the ascending loop of Henle and distal convoluted tubule and modulates epithelial cell growth and metabolism, and plays a role in renal repair following injury.[81,99] EGF is decreased in the urine of children with congenital UPJO, while levels of MCP-1 are increased.[81] Following 5 days of UUO in the neonatal rat, the number of nephrons was decreased despite administration of exogenous EGF. However, tubular vimentin was decreased by one-third, and more importantly, tubular atrophy was reduced by 58% at 1 month following relief of UUO, an effect not seen in control animals.[100] In a similar study, exogenous EGF improved the decrease in renal blood flow in a partially obstructed ureteral

model.[101] Thus, administration of exogenous EGF could potentially slow the deleterious effects of obstruction on the maturing kidney.

Advances in Renal Replacement Therapy

Despite our best efforts, some children will still progress to renal failure secondary to various causes, including obstructive uropathy. Renal transplantation continues to be limited by an organ donation shortage, as well as the effects of organ rejection and the need for multiple organ transplants.[102] Numerous scientific advances in the fields of tissue engineering and stem cell research have given these patients hope that options other than organ transplantation may be available in their lifetimes (Figure 19.2).[103] Unfortunately, kidney reconstitution is difficult because in addition to excreting urine, there are many metabolic and endocrine functions of the kidney that maintain body homeostasis.[104] Stem cell therapy has been the headliner over the past few years, and significant advances have been made. Different sources of stem cells include embryonic and adipose tissue, and specifically for renal regeneration include bone marrow and amniotic fluid stem cells.[105] Animal models have shown recovery of renal function after injection, but how these cells are working has yet to be elucidated completely at this time.[106] As with any new treatment, long-term effects should not be overlooked, and this still remain unclear. While the use of stem cells and their advances in discovery may be potential therapies, questions still remain as to what type of stem cell and the best course of delivery.

Hammerman stated, "In order for glomerular filtration, reabsorption, and secretion of fluid and electrolytes to take place in a manner that will sustain life, the nephrons must be integrated in three dimensions with one another and with a collecting system and that vascularization must occur in a unique organ-specific manner from endothelial precursors that may originate from both inside and outside the developing renal anlage."[107] Initial studies confirmed that implantation of developing nephrons into the cortex of newborn mice resulted in differentiation and growth of the donor nephrons. Incorporation of these nephrons, however, into the host collecting system was not seen.[108,109] Studies have also shown that human fetal kidney tissue grafted under the renal capsule of immunodeficient rodents evoked a lower immune response compared with grafting adult renal tissue.[110] In addition, the fetal kidney has the potential to not only incorporate growing vessels from the developing abdominal aorta, but also attract its own vasculature in situ, which is important in terms of maintaining viability during transplantation.[111] Transplantation of a developing embryonic rat kidney into the omentum of an immunocompetent rat following unilateral nephrectomy resulted in increased renal growth, maturation of tubules and glomeruli, and incorporation of host blood supply from the superior mesenteric artery.[112] More importantly, survival in an anephric rat was prolonged to 7 days by this transplanted kidney.[113,114]

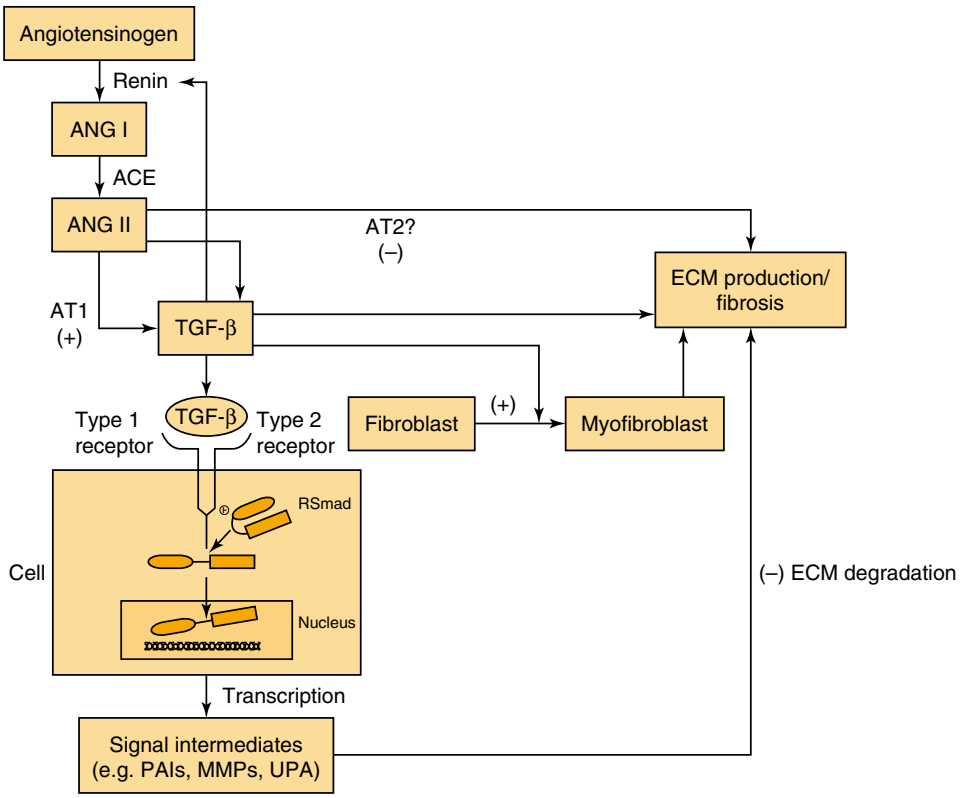

FIGURE 19.2 Summary of the roles played by the renin–angiotensin system, TGF-β, and TGF-β-downstream signal mediators in tissue fibrosis. ANG 1, ANG II, angiotensin I and II; ATI, AT2, angiotensin type 1 and 2 receptors; RSmad, receptor-activated *SMAD*; ECM, extracellular matrix; PAIs, plasminogen activator inhibitors; MMPs, matrix metalloproteinases; UPAs, urokinase-type plasminogen activators.

Finally, in an attempt to find a more physiologic, yet still extracorporeal, alternative to dialysis, Humes et al. developed an artificial kidney that maintained the metabolic, endocrinologic, and filtration demands in acutely uremic dogs.[114] This "kidney" consists of a synthetic hemofiltration cartridge with a renal tubule cell-assist device (RAD) in which human renal tubule cells have been grown to confluence along the inner surface of the hollow fibers.[114,115] A recent Phase I/II FDA-approved trial using this device in intensive care unit (ICU) patients with acute renal failure showed that this experimental therapy could be delivered safely for up to 24 hours.[115]

Based on the above examples, there clearly has been tremendous effort by investigators concerning research in organ replacement and regeneration. Ongoing research is needed in these areas, as they may someday represent viable alternatives to renal transplantation in humans.

Renal Physiology: The Basics

Much like basic science of the kidney, renal physiology is quite complex, and this will be a simple review targeting urologists as the primary audience and focusing on the basic fundamentals required in understanding various urologic conditions. The basic functioning unit of the kidney is the nephron, with tasks including filtration (most important), reabsorption, secretion, and excretion. The kidney receives approximately 20%–25% of cardiac output, and renal blood flow is directly proportional to the pressure difference between the renal artery and vein. As mentioned, filtration is the most important function of the kidney, and the GFR is 125 mL/min in males and 100 mL/min in females. GFR is a reflection of overall renal function, which includes regulating total body salt and water content, managing electrolytes, and eliminating waste of protein metabolism.[116,117] GFR is estimated with serum creatinine and blood urea nitrogen, but more accurate is the 24-hour creatinine clearance, as estimated by the Cockcroft–Gault formula: CrCl (mL/min) = ([40 – Age] × ([Ideal body weight in kg])/(Plasma creatinine [mg/dL × 72]) × 0.85 (women).[118,119]

The RAS has been a target in renal fibrosis after obstruction, and renin is secreted by macula densa cells in the kidney at the detection of decreased blood pressure.[120] The action of angiotensin II is to increase intravascular volume through vasoconstriction of the efferent arteriole, thus increasing blood pressure. In addition to acting on the central nervous system to increase antidiuretic hormone (ADH) from the posterior pituitary, it increases aldosterone secretion from the adrenal cortex.[121]

The renal tubule has two primary roles, to reabsorb and secrete substances, and each section has a different function. The proximal tubule is responsible for the majority of reabsorption (60%), including sodium, chloride, bicarbonate, and water. The loop of Henle's job is to reabsorb NaCl in excess of water to create a high interstitial osmolality, allowing maximal urinary concentration, known as the countercurrent multiplier. The distal tubule primarily reabsorbs calcium and sodium, and the collecting duct is for fine tubing, and reabsorption of water is regulated by vasopressin (ADH).[122]

Finally, renal physiology pertinent to the urologist would not be complete without briefly mentioning renal tubular acidosis (RTA). The most common form, RTA Type 1 (distal), poses the most significance to urologists, as these patients have approximately a 75% chance of developing stones. This results from impaired distal tubular excretion of H+, and thus patients will have hypokalemia, hyperchloremia, and a nonunion gap metabolic acidosis.[123] Urine will be alkaline with hypocitraturia and high calcium. Stones are typically calcium phosphate, and urine pH will be >5.5. Treatment is with oral alkalization and citrate. RTA Type 2 (proximal) patients do not have stones, as their citrate is normal and results from failure of bicarbonate reabsorption in the proximal tube. This is more common in children, and patients may have growth retardation and metabolic bone disease. Treatment is with sodium bicarbonate. Lastly, RTA Type 4 is secondary to impaired cation exchange in the distal tube, with decreased secretion of hydrogen and potassium; thus, this is the only type of RTA with hyperkalemia, and treatment is aimed at reducing potassium.

CONCLUSION

Prevention of nephropathy will continue to be a major focus of pediatric urology clinicians and researchers. The goal of this chapter was to identify and discuss general areas of importance where research of multiple types can make a clinical impact. However, the information given is only a snapshot of selected research contributions and in no way represents the vast and continuous efforts by other investigators in the field. The potential of molecular biomarkers to serve as prognostic indicators of cellular damage is at the forefront of renal research. As technology diversifies, new research opportunities will also continue to materialize. These may include the use of genetically engineered animal models, targeted gene therapies, or improved surgical procedures with miniaturized instrumentation or the use of robotic assistance.

Although currently we cannot prevent renal failure, research in the laboratory has given us valuable insight into normal and abnormal renal development, mechanisms underlying renal damage, and new ways to administer renal replacement therapy. Open communication between clinicians and researchers, as well as the increased training of physician-scientists, will help fuel future research possibilities. In the end, what is learned in the laboratory will continue to be translated into a better quality of life for our patients.

CHAPTER 20

Renal Vasculature and Kidney

Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

The gross anatomic development of the primitive vasculature forms during the first three gestational weeks. Angioblasts form from mesenchymal cells that separate from the primary trophoblast at the same time as other mesoderm is forming. These angioblasts appear in the body stalk and form isolated vascular spaces or blood islands, which become lined with endothelium,[1] and the eventual growth and union of these isolated spaces form plexi that eventually unite to form a system of closed vessels. Mesenchyme laid down around the endothelium forms the intima, media, and adventitia of the vessels. Once this system of closed vessels is in place, any new vessels that arise are outgrowths of existing vessels. Definitive vessels arise by selection, enlargement, and differentiation. The selection of resulting channels occurs through inherited patterns and hemodynamic factors. Vasculogenesis factors, such as vascular endothelial growth factor (VEGF) and erythropoietin (EPO), have been extensively studied in various animal models, with studies ongoing to correlate with human embryogenesis and fetal placental angiogenesis.[2–4] Additionally, it is hypothesized that renal vasculature formation may depend on migration of renal tissue endothelial stem cells. This is opposed to how other organs, such as the placenta, develop, where the epithelial cells acquire the endothelial phenotype during formation, rather than by migration of endothelial stem cells themselves.[5] It is during this period that paired dorsal aortae arise. In addition, paired postcardinal veins form to return blood to the heart from the caudal end of the body via a common cardinal vein. The postcardinal veins develop as the mesonephroi vessels and run dorsal to mesonephroi. The previously paired dorsal aortae fuse at the level of the fourth thoracic vertebra to the fourth lumbar vertebra to form a single descending aorta in the fourth week. Lateral branches of the dorsal aorta appear during the fifth week. These irregularly segmented vessels supply those structures arising from the nephrotome region, specifically the mesonephros, gonads, metanephros, and suprarenal glands. The number of lateral branches is reduced during involution of the mesonephros, with the lateral branches ultimately becoming the inferior phrenic, adrenal, renal, and gonadal arteries.

During the sixth week, the inferior vena cava formation starts (Figure 20.1). Subcardinal veins develop ventromedial to the mesonephros and connect with each other and with the postcardinal veins. The posterior cardinal veins, which supply the mesonephric kidneys, ultimately disappear when the mesonephroi involute; remnants of the posterior cardinal veins will become the root of the azygos vein and the common iliac veins.[1] Supracardinal veins develop dorsomedially to the postcardinal veins and will replace them. This process continues during the sixth to the eighth week of gestation, until the formation of the inferior vena cava is complete. *Connections between the subcardinal veins persist as a common stem uniting the left renal vein, the left adrenal vein, and the left gonadal vein to the vena cava. The right subcardinal vein forms the inferior vena cava at the level of the renal veins and the vena cava cephalad to the renal veins; this explains why the right adrenal vein and the right gonadal vein drain directly into the inferior vena cava.* The right supracardinal vein also persists as the inferior vena cava below the renal veins; the left supracardinal vein disappears entirely.

Although there are many normal variations in renal arterial supply, most tend to be variations of the arrangement of five segmental arteries: posterior, upper anterior, middle anterior, apical, and inferior polar.[6] During renal ascent from the pelvis, the developing kidneys receive their blood supply from the vessels that are closest to them. Normal ascent stops where the kidneys meet the adrenal (suprarenal) glands. The blood supply to the kidneys initially comes from the common iliacs but will ultimately arise from branches off the aorta. Earlier blood vessels used during renal ascent will involute and disappear unless ascent is incomplete (Figure 20.2).[1] Accessory renal arteries arise if some precursors do not involute; most arise from the aorta either superiorly or inferiorly. Accessory arteries are present in about 25% of adult kidneys and are more common than accessory veins (Figure 20.3). Obstruction of the proximal ureter can occur if an inferiorly placed accessory artery is present and if that artery crosses over the ureter.

Persistence of the right subcardinal vein as the inferior vena cava rather than the supracardinal vein results in a retrocaval ureter. All reported cases of retrocaval ureter have been right-sided except when situs inversus is present.[7]

Retroiliac ureter is a rare anomaly that may result if the iliac artery should form from a ventral root of the umbilical artery rather than a segmental branch of the aorta, as it normally does in the fourth week.[8]

DEVELOPMENT OF THE NORMAL GLOMERULUS

The glomerulus develops when the metanephric mesochyme mesoderm induced by the ureteral bud forms S-shaped bodies, which will become the future nephrons.

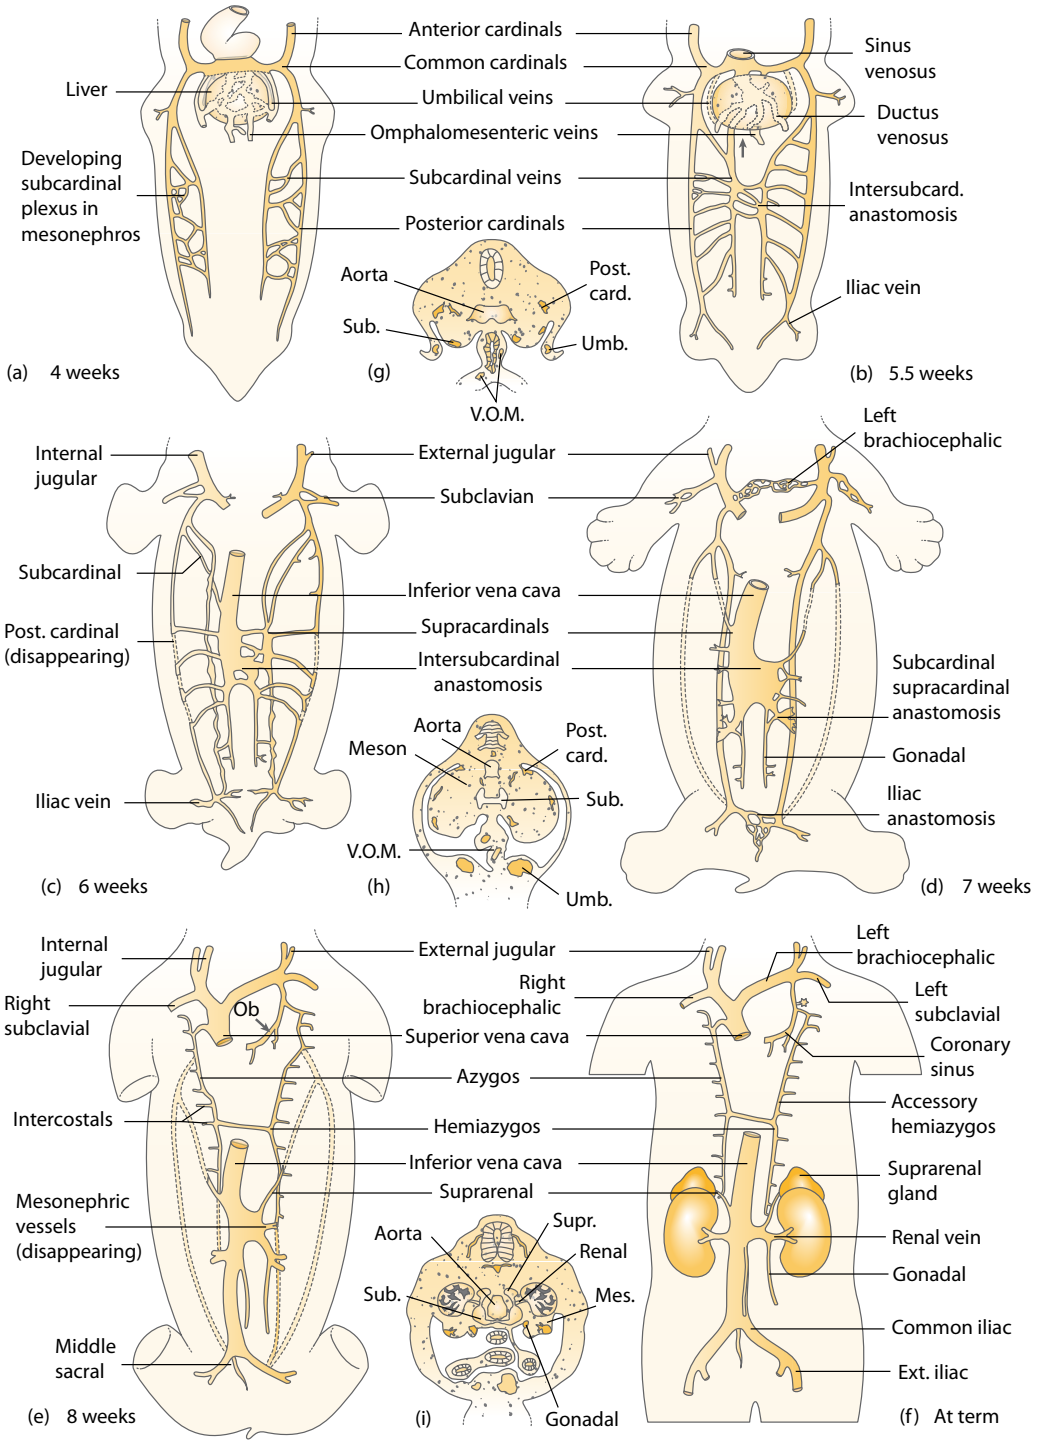

FIGURE 20.1 Development of the superior and inferior vena cava. (a–f) anterior views; (g–h) cross-sectional views. V.O.M., omphalomesenteric veins. (Adapted from Pattern W Jr. *Human Embryology*. New York: McGraw-Hill, 1976.)

These S-shaped structures are invaded by nearby blood vessels, forming the glomerular tuft. Glomerular formation occurs throughout gestation, starting sometime after 8 weeks, as demonstrated on immunohistochemical studies on autopsies done on fetuses from 8 weeks' until 40 weeks' gestation. Fonseca Ferraz et al. performed morphometric analyses on 86 fetal kidneys obtained during autopsy.[5] They found that nephrogenesis stopped between 32 and 36 weeks gestation. The nephrogenic zone, the area of the renal cortex that is closest to the capsule, where glomeruli present in S form, decreases with increased gestational age. As the nephrogenic zone decreased, the capillary tuft size of the intermediate glomeruli increased as well. This increase in the capillary tuft was not seen in the juxtamedullary or superficial glomeruli.[5]

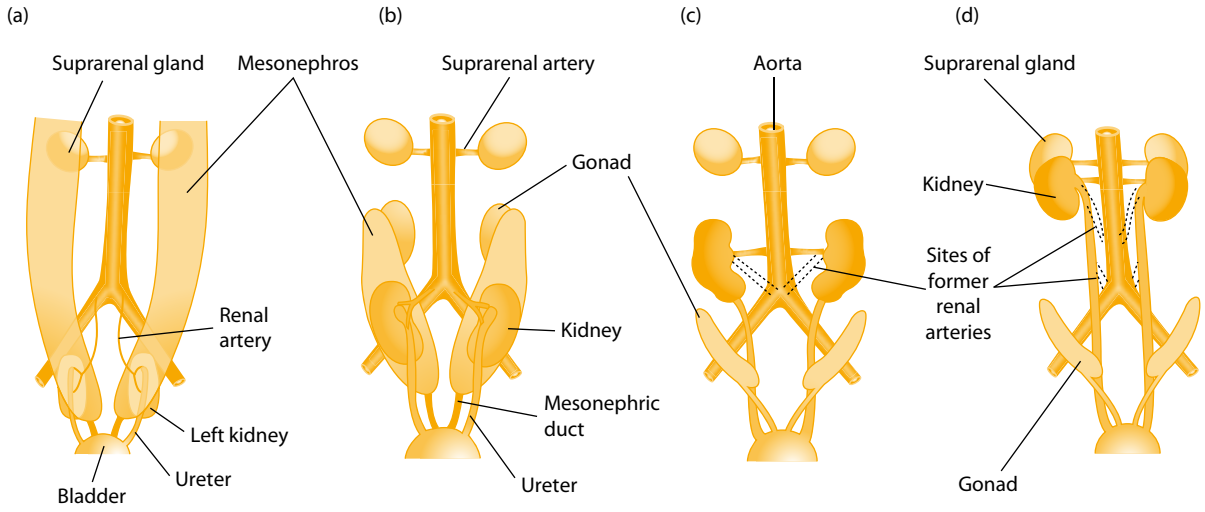

FIGURE 20.2 Ascent of the kidneys. (a–d) Diagrammatic ventral views of the abdominopelvic region of embryos and fetuses (6th–9th weeks) showing medial rotation and 'ascent' of the kidneys from the pelvis to the abdomen. (a and b) Observe also the size regression of the mesonephroi. (c and d) Note that as the kidneys 'ascend,' they are supplied by arteries at successively higher levels and that the hilum of the kidney (where the vessels and nerves enter) is eventually directed anteromedially. (Reproduced with permission from Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*, 7th edn. Philadelphia: Saunders, 2003.)

Wilms' tumor suppressor gene (WT1), which encodes a zinc finger transcription factor, is an important regulator of development of the metanephric kidneys. Kim et al. found WT1 in the developing glomeruli, in the comma and S-shaped bodies, and in the podocytes of the mature glomeruli. They postulate that the WT1 gene is required for the induction signal promoting the ureteral bud invasion of the metanephric mesenchyme. Many of the WT1 target genes were found to induct growth factor and membrane signaling pathways for renal development.[9]

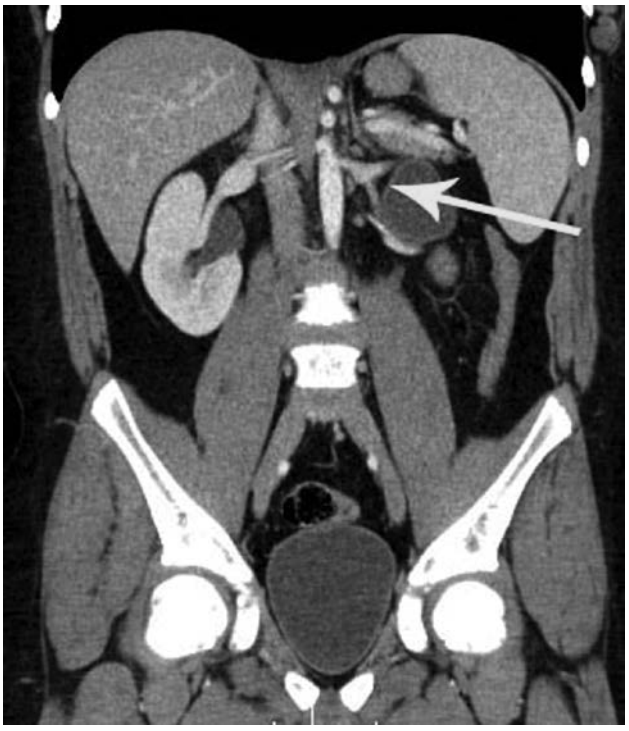

FIGURE 20.3 CT image of accessory crossing renal vessels causing ureteropelvic junction obstruction.

KIDNEY AND URETER

The urogenital system develops from the intermediate mesoderm arising from the dorsal body wall but will ultimately be ventrally located as a result of embryonic folding. This mesoderm arising on either side of the descending aorta will form the urogenital ridge. The urinary system starts developing before the genital system.[1]

There are three sets of kidneys that develop in mammalian embryogenesis. The first to form, during the first 21 days of development, are the pronephroi. These nonfunctioning units arise in the cervical and thoracic region of the embryo (Figure 20.4). The pronephros does not function in mammals but is analogous to the kidney in primitive fish. Seven pairs of tubules arise as dorsolateral sprouts from segmentally arranged nephrotomes (specialized areas of mesoderm). As the last tubule appears, the earliest is degenerating. The distal ends of these tubules bend dorsally, canalize, and unite one with another into a longitudinal collecting duct. This collecting duct eventually reaches the cloaca and communicates with it. The pronephric ducts persist and are necessary for the next interim kidney development. If the pronephros or its duct does not develop, the mesonephros will not form.

Late in the fourth gestational week, the mesonephros arises from nephrotomes caudal to the pronephros; these nephrotomes are unsegmented, unlike the pronephric nephrotomes. The mesonephric mesoderm separates into a longitudinal bar termed the nephrogenic cord. Within this cord, the mesenchyme forms into tubules. As one end of the tubule becomes associated with a knot of blood vessels, the other opens into the original pronephric duct, now called the mesonephric duct. With this process,

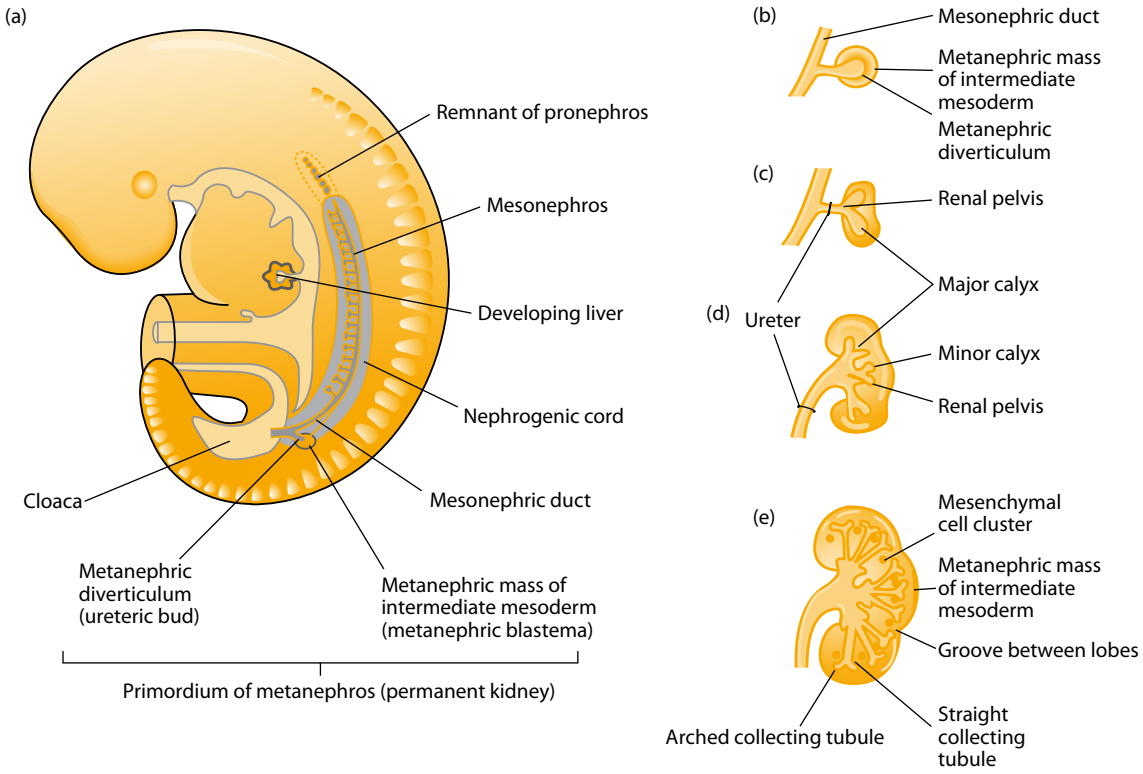

FIGURE 20.4 Development of the permanent kidney. (a) A lateral view of a 5-week embryo, showing the primordium of the metanephros. (*b–e*) Successive stages in the development of the metanephric diverticulum or ureteric bud (5th–8th weeks). Observe the development of the ureter, renal pelvis, calices, and collecting tubules. (Reproduced from Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*, 7th edn. Philadelphia: Saunders, 2003. With Permission.)

the nephrogenic cord becomes subdivided into spherical masses of cells that appear progressively from its cranial end to its caudal end. These masses will hollow and send out solid extensions that unite with the mesonephric duct. These solid extensions canalize and, with linear growth, bend into an S shape, forming the S-shaped bodies. Nearby tufts of capillaries form the glomerulus, which then indents the free end of the S-shaped tubule, becoming Bowman's capsule (Figure 20.5). Bowman's capsule and the glomerulus together make up the mesonephric corpuscle. Lateral branches of the aorta feed the glomerulus, while the postcardinal veins drain these tubules by sinusoids. The mesonephric tubules between the mesonephric duct and the glomerulus elongate and form a secretory segment and a collecting segment. As the tubules enlarge, the nephrogenic cord bulges into the coelom, forming a urogenital ridge on each side of the dorsal mesentery extending roughly from the diaphragm to the cloaca (Figure 20.6).

Programmed cell death, or apoptosis, occurs at set stages of renal development and is necessary for normal development and regression of the three forms of embryonic kidneys. Grossly, the pronephric tubules have completely degenerated by the fourth week, but the pronephric duct persists as the mesonephric (Wolffian) duct. The mesonephros begins to reach its stage of maximal development by the 28th day, with about 30 tubules in each mesonephros. The cranial tubules of the mesonephros degenerate, while others are forming caudally. Unlike the pronephroi, the mesonephroi are well developed and will function as interim kidneys for about 4 weeks. The glomeruli in animals studied (rabbits, cats, and pigs) can excrete ferrocyanide at this stage, while the tubules can secrete phenol red. At the caudal end of the nephrogenic cord, at the level of the sacral vertebrae deep in the pelvis, the metanephros soon appears as a metanephrogenic mass (nephric blastema).

The mesonephric duct makes a sharp bend before it enters the cloaca (Figure 20.4). The ureteric bud, which will become the ureter, renal pelvis, calices, and collecting ducts, arises from the dorsal medial aspect of this bend. It hollows and grows dorsally and then cephalad. It pushes into the metanephric blastema mass, composed of intermediate mesoderm, and separates from the nephrogenic cord. The interaction between the ureteric bud and the metanephric mass begins to induce nephrogenesis. The proximal end of the ureteric bud elongates to form the ureter, while the distal end, that portion pushing into the metanephrogenic mass, becomes the renal pelvis. The metanephric blastema mass surrounds the renal pelvis like a cap.

In the fifth week, early development of the permanent kidney is occurring, having been induced by the key union of the ureteric bud with the metanephrogenic mass. *The kidney is initially oriented in an anteroposterior direction, with the ureter entering the hilum of the kidney anteriorly* (Figure 20.2). With elongation of the ureter and straightening of the body, the kidney "ascends" from its pelvic position to its eventual normal site, just below the

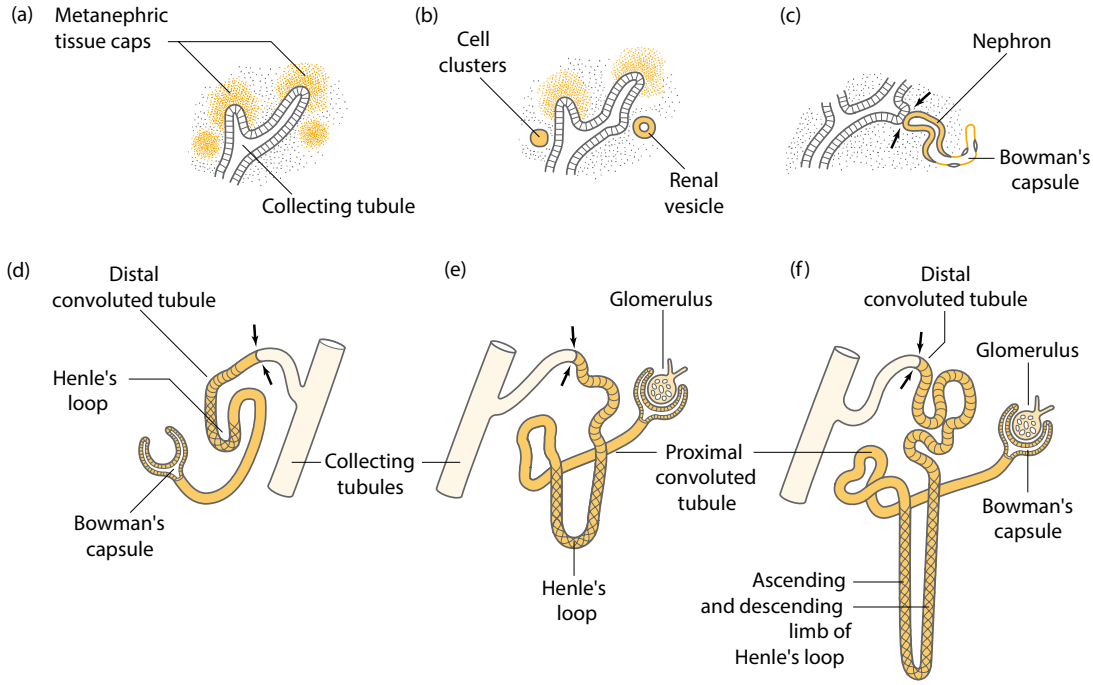

FIGURE 20.5 Development of a metanephric unit. Arrows indicate the place where the excretory unit establishes an open communication with the collecting system, thus allowing the flow of urine from the glomerulus into the collecting ducts.

suprarenal or adrenal glands; during the fifth week, however, the kidney is still caudal to the umbilical arteries. Late in the fifth week, the kidney begins to turn 90° on its vertical axis so that, ultimately, its dorsal border becomes its lateral border.

By the sixth week, the kidney has ascended sufficiently so that it lies cephalad to the umbilical artery. The renal pelvis flattens and divides into two major calices. By the seventh week, the kidney comes into contact with the suprarenal body and shortens and widens; by the eighth week, the center of the kidney has reached its permanent level opposite the second lumbar vertebra. The caudal pole is above the iliac vessels and the cranial pole below the suprarenal gland (Figure 20.2).

Cell proliferation is obviously also integral to renal development and differentiation. Ki-67 is a nuclear protein expressed in all stages of the cell cycle except for the resting phase and is used as a cell proliferation marker. Ki-67 is found in early metanephros development between 5 and 7 weeks. Measuring this protein increase during gestation weeks 5–7 shows the role of cell proliferation during branching of the ureteral bud and early nephron formation.

p53 genes and caspase-3 are found during apoptosis. Carev et al. found increased levels of these proteins and genes in the regressing mesonephros, as Ki-67 protein was found to increase in the developing metanephros.[10] The mesonephros completely regressed by the 16th week of gestation, as found by measuring p53 and caspase-3.[11]

From the 6th to the 20th week, the major calices progressively subdivide through 12 generations. The second, third, and fourth generations enlarge and fuse to form approximately nine minor calices. The fifth generation of

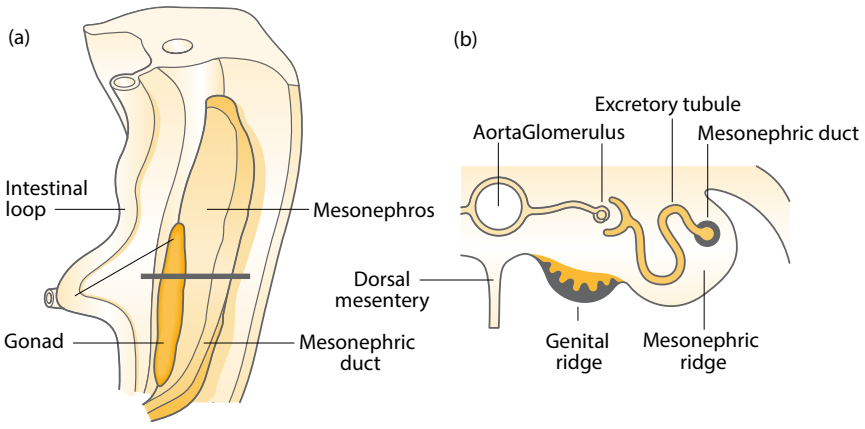

FIGURE 20.6 (a) Relationship of the genital ridge and the metanephros. Note the location of the mesonephric duct. (b) Transverse section through the mesonephros and genital ridge at the level indicated in (a).

branches (about 25 in number) form papillary ducts, emptying into the minor calices. The 6th to 12th branch generations form the collecting ducts in the renal medulla and project into the renal cortex. All the tubules draining into a minor calyx comprise a renal pyramid, the base of which adjoins the renal cortex, while its apex (papilla) projects into a calyx. The calices, pelvis, and ureter differentiate into transitional epithelium and become invested with smooth muscle and connective tissue by specialization of the surrounding mesenchyme during the eighth week.

The cap of metanephrogenic tissue that covers the ureteral bud has two layers: an external layer, which forms the renal capsule and connective tissue, and an inner layer, which forms the nephrons. The inner layer divides as the renal pelvis branches, so that a small cap of metanephrogenic tissue covers each subdivision through all 12 generations. As the renal cortex organizes, the region over each pyramid is demarcated from the next pyramid, so that as many as 20 lobes are formed. This lobation disappears progressively in infancy and early childhood but may be readily apparent on routine ultrasonographic examination as fetal lobulations, especially in infants.

During the seventh week, the inner layer of the metanephrogenic tissue begins to condense into spherical masses about the ends of the branches of the ureteral bud. These masses hang down into the angles between the branches. As the cortex thickens, new spheres form. The spheres change into vesicles and elongate, producing an S-shaped tubule, which unites with a collecting tubule. The blind end of the secretory tubule becomes the Bowman's capsule, while the midportion elongates and twists. An afferent arteriole grows in, the glomerulus differentiates, and an efferent arteriole grows out. The combination of the developing elongating metanephric vesicles that become the metanephric tubules and the glomerulus with Bowman's capsule ultimately form the nephron. Nephrogenesis starts in third-generation ureteral branches in the midportion of the kidney and in fifth-generation branches at the poles. *Nephrogenesis, or formation of nephrons, continues through the 36th week of gestation and then ceases. Although the number of nephrons does not increase with age, the size of the nephron increases throughout somatic growth.*

The fetal kidney is capable of secretion by the 10th week of gestation, and urine is produced. The bladder fills and urine is voided into the amniotic sac. The amniotic fluid is imbibed by the fetus and is an important factor in pulmonary maturation. A mature fetus can swallow several hundred milliliters a day, which is then absorbed by the fetal intestines. Fetal waste products are transferred through the placenta into the maternal circulation for disposal.

Scientific research has been quite extensive in human and animal models concerning the molecular control and triggering of embryonic development. Previously, normal renal development was thought to hinge on the metanephric diverticulum or ureteral bud making contact with the metanephric mass. Currently, embryonic renal development is thought to be due to signals from adjacent tissues, and coordination of normal organ development depends on appropriate interactions between constituent parts at the appropriate time for that development.[1]

Mesenchymal–epithelial interactions are crucial for the development of the branching organs, as in the kidneys, lungs, pancreas, and salivary glands. Molecular studies have shown that glial cell line–derived neurotrophic factor (GDNF), a transforming growth factor β (TGFβ), signals development of the ureteral formation and budding necessary to form the branching of the ureteral bud necessary for renal development. GDNF signals the branching using a receptor tyrosine kinase (Ret) and a glycophosphadidylinositol (GPI)-linked surface coreceptor, Gfrα1.

GDNF is expressed only in the metanephric mesenchyme adjacent to the caudal portion of the Wolffian duct, and Ret is expressed only at the distal tips of the ureteral bud. If GDNF, Ret, or Gfrα1 is absent, the ureteral bud will not form. About 40% of cases of renal agenesis in humans are found to be associated with Ret mutations and 5%–10% with GDNF mutations. Additionally, the formation of a single, appropriately located ureteral bud depends on correct GDNF regulation. GDNF also regulates restriction of budding of the Wolffian duct as to form a single ureter signaling the Sprouty 1 negative regulator enzyme[11] (Figure 20.7).

GDNF alone is not critical for branching of the ureteral bud, but GDNF triggering Ret, specifically located at the tips of the ureteral bud, allows for branching of the nephrons and collecting system. Sprouty 1 helps regulate the amount of branching as appropriate for the developing kidney. Ret signaled by Wolffian duct cells allows Ret active cells to move past other mesodermal cells in the Wolffian duct to form the first ureteral bud tip[12] (Figure 20.8).

The renin–angiotensin system also plays a critical role in the interaction between the ureteral bud and the metanephros. Angiotensin II (Ang II) also stimulates ureteral bud branching via c-Ret activation pathways. The absence or abnormal functioning of the pathways leads to aberrant ureteral bud development and branching, causing congenital abnormalities of the kidney and urinary tract (CAKUT).[13] CAKUT was coined by several urologists and nephrologists who found that there was divergence between the two communities concerning the causes of abnormal development of the kidneys and urinary tract. This combined system approach of nephrology and urology research concerning developing kidney pathways relating to the developing ureteral system pathways and their complementary effects may explain the various malformations that occur due to aberrant reciprocal induction in the urinary system.[14]

Major investigation in CAKUT has identified specific genes (PAX-2 and EYA1) responsible for the anomalies found in the developing kidney and ureteral bud.[15] Other molecules regulate nephron induction, such as TGFβ2 and bone morphometric proteins (BMP-7), and nephron maintenance and differentiation, such as fibroblast growth factor-2 (FGF-2) and leukemia inhibitory factor (LIF). Still other molecules, including PAX-2, BCL-2, ANG2 (Angiotensin 2), and hepatocyte growth factor (HGF), are thought to regulate apoptosis of the developing kidney tubules and nephrons.[1,16–18]

The PAX-2 gene was the first specific gene with a mutation found to be associated with CAKUT with high autosomal dominant penetrance.[19]

Multiple anomalies result from disordered embryogenesis of the ureter or kidney. Some are known to be familial, at least in some instances (e.g., ureteral duplications and vesicoureteral reflux [VUR]), whereas others are frequently associated with chromosomal abnormalities (e.g.,

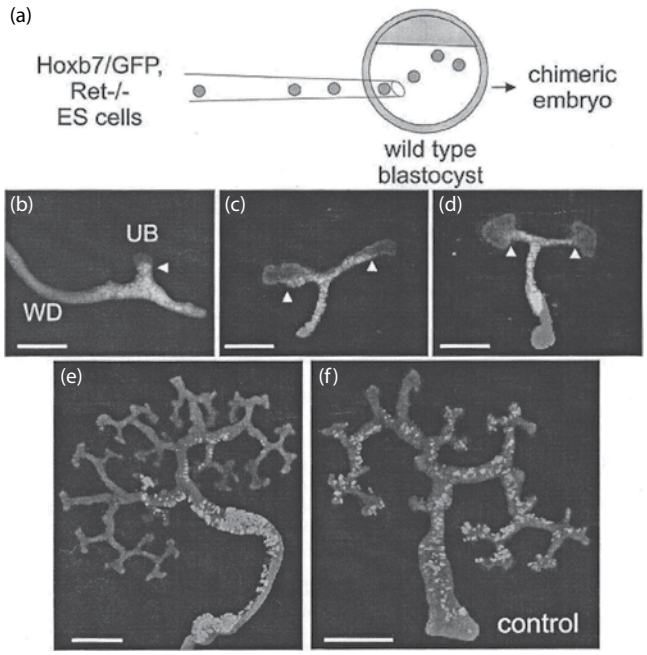

FIGURE 20.7 Inability of Ret$^{-/-}$ cells to contribute to ureteric bud tips in the kidneys of chimeric mice. (a) Generation of chimeric embryos. The embryos were recovered at different stages of ureteric bud outgrowth and branching, the mutant ureteric bud (UB) cells were identified by their expression of GFP, and the UB including wild-type cells was visualized by anti-cytokeratin staining. (b) At E11.0, Ret$^{-/-}$ cells contributed without restriction to the WD and to the trunk of the primary UB, but were excluded from the UB tip. The furthest point at which mutant cells were found is indicated by the white arrowheads. (c) After the first branching event (E11.5), the mutant cells had entered the two new branches, but did not extend all the way to the tips. (d) When the tips swelled to form ampullae, the mutant cells failed to contribute to the ampullae. (e) In an E11.5 kidney cultures for ~3 days, the mutant cells contributed to several generations of branches, but were absent from the more distal branches and all of the tips. (f) Control (Ret +/-, Hoxb7/GFP) ES cells contributed without restriction throughout the ureteric bud tips and trunks. Scale bars, 0.25 mm. (Panels [b-f] Reprinted from *Dev Cell*, 8, Snakya R, Watanabe T, Costantini F. The role of GDNF/Ret signaling in ureteric bud cell fate and branching morphogenesis, 65-74. Copyright 2005, with permission from Elsevier; from Costantini F, Shakya R. *Bioessays* 2006;28:123. With permission.)

horseshoe kidney and Turner syndrome). Most, however, seem sporadic in incidence.

If the pronephrosis fails to develop, the mesonephros will not develop; the result is renal and ureteral agenesis. Unilateral renal agenesis occurs in approximately 1 in 1000 newborns. Males predominate in occurrence, as does a proclivity to the absent kidney being on the left. Additionally, in the male, the ipsilateral genital ducts do not form. *Hence, there is a high association of renal agenesis in patients with congenital absence of the vas deferens.*[20] A similar situation would result if the mesonephric duct failed; however, if the mesonephric duct developed but the mesonephros did not, the kidney would be absent, while the genital ducts, and perhaps a blind-ending ureter, could result. If both kidneys fail to develop, oligohydramnios (due to a lack of fetal urine) produces the deformation

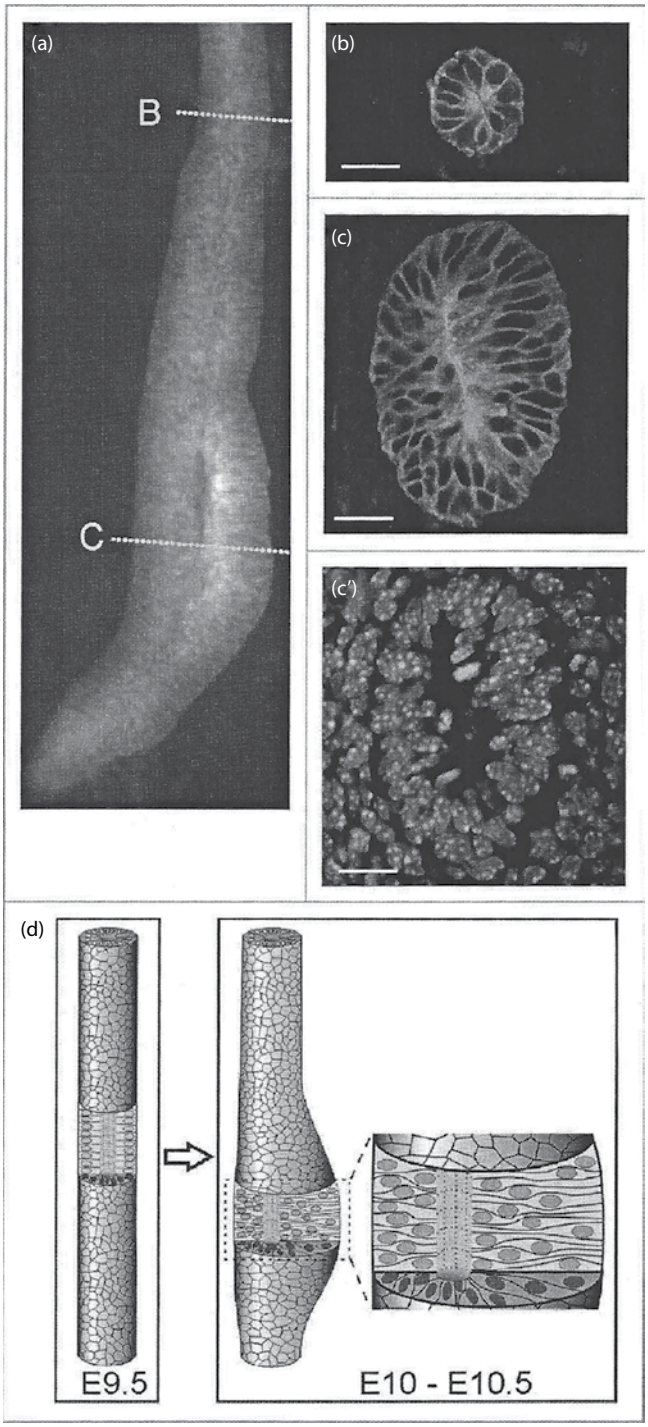

FIGURE 20.8 The nephric duct forms a transiently pseudostratified epithelium before ureteric bud (UB) formation. characteristic of Potter syndrome (characteristic facies with low-set ears, hypertelorism, and flattened nose, as well as limb deformities due to the relative absence of amniotic fluid) and interferes with pulmonary maturation. Occurrence of bilateral renal agenesis is approximately 1 in 3000 live births and is incompatible with postnatal life. Skinner and associates studied human DNA in 33 stillborn fetuses with renal aplasia or severe dysplasia and found Ret mutations in 37% of fetuses with bilateral renal agenesis and in 20% of the fetuses with unilateral renal agenesis. Interestingly, despite the GDNF–Ret association, it is rare to find abnormal renal development due to GDNF mutations. Of note, Ret mutations are also found in patients with Hirschsprung disease.[21]

Failure of renal ascent results in simple pelvic ectopia. Further ascent but failure of rotation is seen clinically as malrotation or incomplete rotation maintaining the normal embryonic anteriorly placed renal pelvis, or overrotation with either a laterally or posteriorly placed renal hilum. Many of these kidneys are also ectopically located. If the two metanephrogenic masses come into contact in the pelvis, they could fuse and form a pancake (lump) kidney. Fusion slightly later, usually in the lower pole of the developing kidneys, might result in a horseshoe kidney. The ascent of the horseshoe kidney is arrested by the inferior mesenteric artery. Horseshoe kidneys occur in about 1 in 500 people. These kidneys have a two to eight times higher risk for Wilms' tumor development than in the general population. The embryogenesis of crossed ectopia is harder to explain, but it may result from lateral bending and rotation of the tail of the embryo, thereby altering the course of ascent. In this way, both ureteral buds might penetrate a single metanephrogenic mass.[22] Supernumerary kidney formation is relatively rare. Formation of this anomaly is due to the division of the ipsilateral ureteral bud (Figure 20.9).

Cystic renal disease can occur with inherited conditions or through disruptions in normal development.

Autosomal recessive polycystic kidney disease (ARPKD) is a recessively inherited autosomal disorder that is reported to occur in 1 out of 6000–14,000 pregnancies. These kidneys are quite large and may replace most of the retroperitoneum. The cysts are due to enlargement of the collecting ducts; associated liver disorders with periportal hepatic fibrosis are also seen with this disorder. Those infants who do not survive infancy expire due to renal or pulmonary failure. Imaging of ARPKD kidneys with ultrasonography or postnatal computed tomography (CT) is characterized by very large kidneys with a streaking sunburst pattern (Figure 20.10).

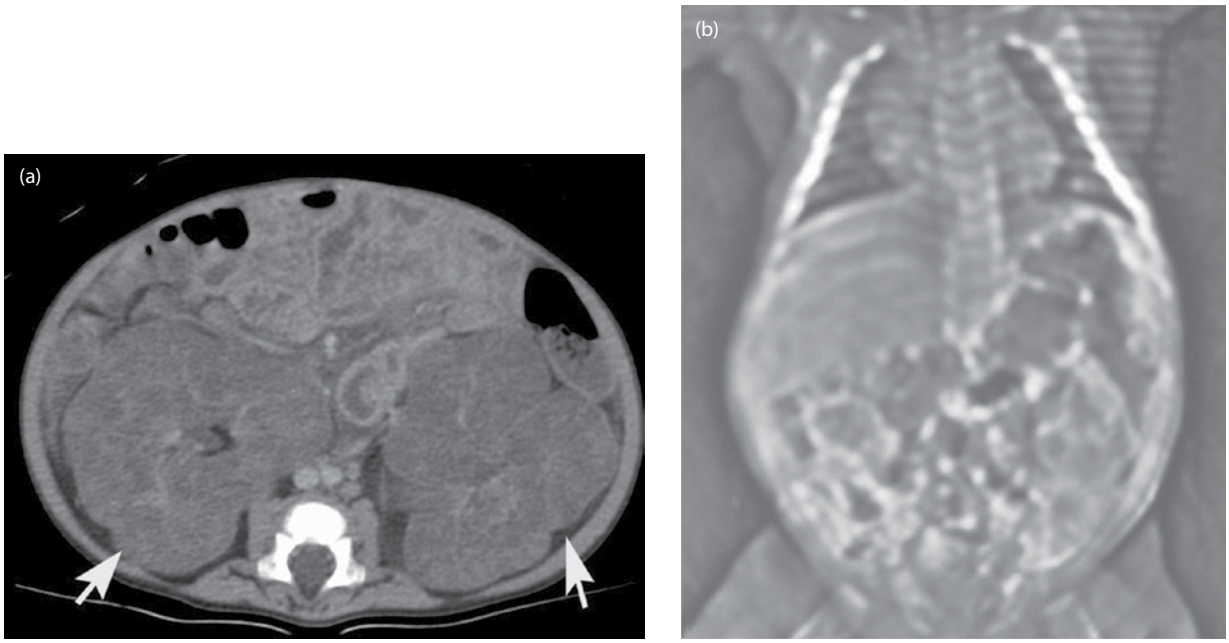

FIGURE 20.10 (a) CT image of ARPKD: note sunburst streaking pattern (arrows). (b) Composite image on CT demonstrates a large abdomen.

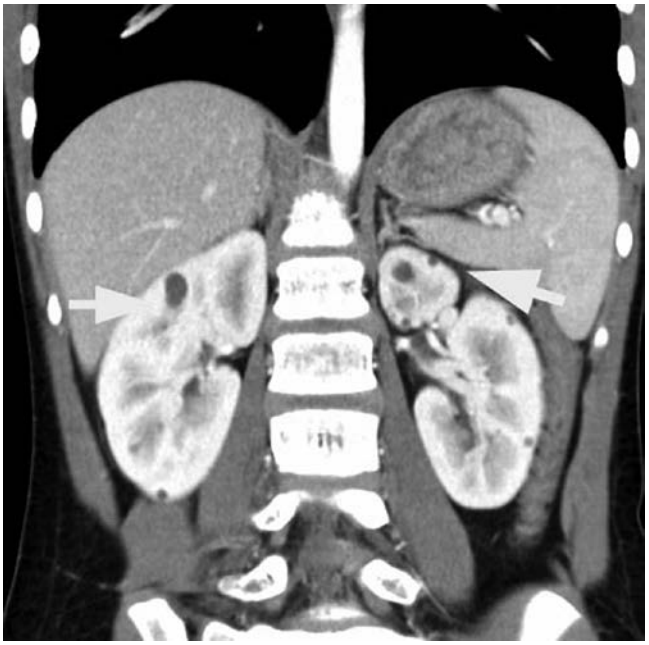

FIGURE 20.11 CT image of ADPKD.

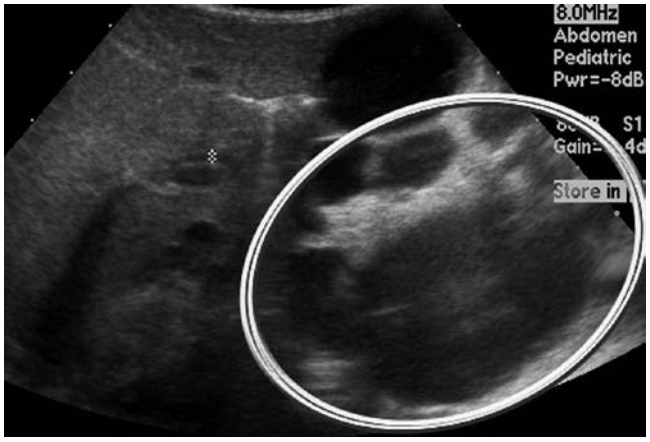

FIGURE 20.12 Ultrasound image of MCDKD.

Autosomal dominant polycystic kidney disease (ADPKD), which is more common than the recessive form, is characterized by cysts forming through abnormal branching of the collecting ducts, as well as cysts forming in other portions of the tubules (Figure 20.11).

Multicystic dysplastic kidney disease (MCDKD) has been said to result from early ureteral obstruction[23] or may result from disordered induction of the metanephrogenic mass by a faulty ureteral bud (Figure 20.12).[24] Complete involution of the cystic components of the multicystic kidney also accounts for some cases of renal agenesis. MCDKD is the most common form of cystic disease, with a frequency of 1 in 3000 pregnancies. In this disorder, there is no recognizable renal tissue present on gross examination, but there may be some dysplastic renal tissue interspersed with the cystic elements. Bilateral MCDKD is incompatible with life, but approximately 75% of cases are found with unilateral MCDKD involvement. These kidneys can be found with antenatal ultrasonography (Figure 20.9). Cysts in this case are thought to be due to dilations of the tubules, especially the loops of Henle.

Embryonic development theory suggests that normal nephrogenesis is dependent on the ureteral bud meeting the center of the metanephrogenic mass so that nephrogenesis is induced by the ureter.[25,26] Should they not meet at all, a blind-ending ureter would result. However, should they meet in an abnormal (degenerating) part of the metanephrogenic mass, renal dysplasia would be anticipated.[26,27] Pathogenesis of dysplastic kidneys has been studied extensively using animal models of urinary tract obstruction at various times in fetal gestation. Kitagawa et al. developed a model for MCKD by ligating fetal lamb urethras at various times during gestation. They found a dysplastic kidney to be pathologically similar to a multicystic kidney when the urethras were ligated at 60 days' gestation, well after the glomeruli started producing urine.[28] Recent human fetal tissue studies using three-dimensional histologic analysis theorize other etiologies for renal dysplasia from urinary tract obstruction causing two different types of dysplasia, MCDKD models and obstructive renal disease models, rather than the abnormal induction of the metanephric mass by the ureteral bud. Shibata and Nagata used human fetal renal tissue and felt that the cystic dysplasia occurred earlier in gestation in MCDKD since cystic areas appeared to decrease with increased gestational age, while interstitial dysplastic tissue increased with later gestational age. They found that cysts were more peripherally located with obstructive renal disease, and the rest of the kidney architecture was generally normal. They theorize that these cysts developed later in gestation because the effect of obstruction of the urinary tract occurs lower and must affect the urethra, bladder, ureter, or renal pelvis before it affects the developing nephrons. In MCDKDs, the obstruction is associated with pyelocalyceal obstruction, which is much higher in the urinary tract, and therefore will have an earlier dysplastic effect on the kidney.[29,30]

Congenital urinary tract obstruction develops with errors in induction of the metanephros and formation of urinary drainage, and through faulty maturation of the pyeloureteral peristaltic mechanism. Generally, anomalies in ureteral bud position, number, and abnormal connections between the ureter and the bladder lead to urinary tract obstruction. Defects in development of the kidney are primarily responsible for urinary tract obstruction, but abnormal remodeling of the lower urinary tract may also be responsible for lower urinary tract anomalies (VUR and ureterovesical obstruction). Faulty development of the pyeloureteral pacemaker cells may lead to ureteral obstruction by failure of unidirectional peristalsis allowing appropriate drainage of the upper urinary tract down the ureter to the bladder[31] (Figures 20.13 and 20.14).

Sonic hedgehog (Shh) gene inactivation is also responsible for defective ureteral mesenchymal differentiation with resultant hydroureter.

Recently, the focus of abnormal urinary tract development has been on associated progressive renal deterioration and renal failure in childhood and adulthood. Dysmorphic kidneys associated with VUR were thought to be due to sterile reflux. Reviews of ultrasonographic and renal scintigraphy without infection make inherent renal dysmorphism during development a more likely causative factor for the defects found. Furthermore, it has been found in

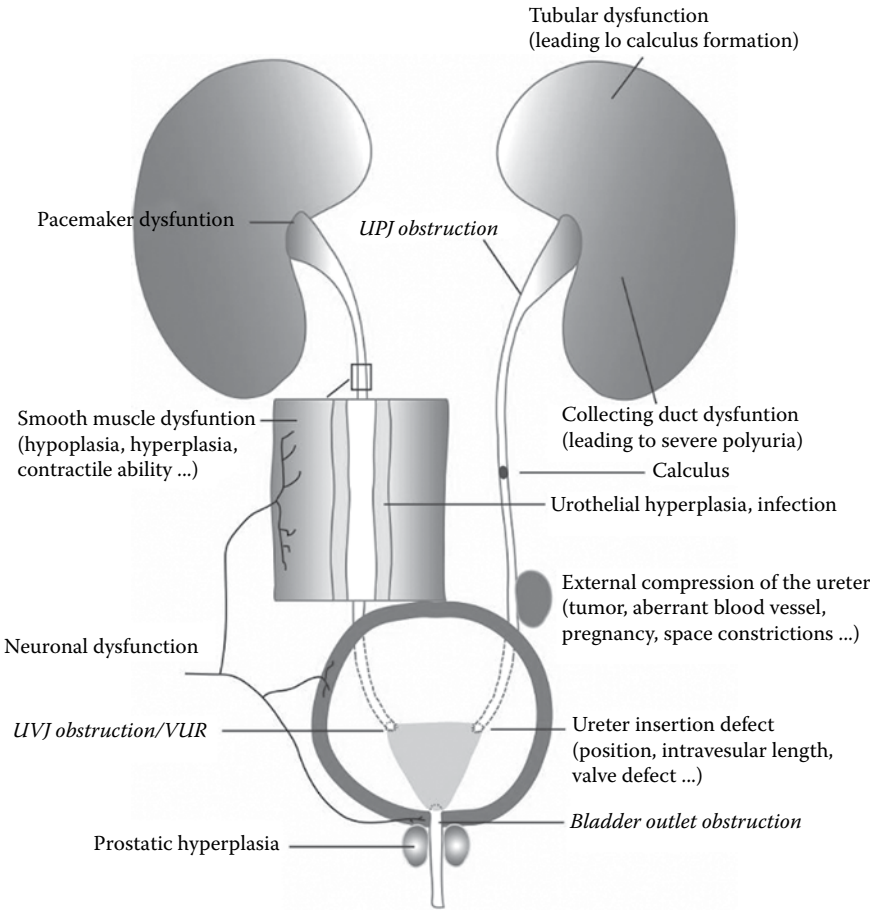

FIGURE 20.13 Causative factors for urinary tract obstruction. UPJ, UVJ and bladder outlet obstruction are in italics as these terms describe the location but not the causes for the obstruction. (From Chen F. *Pediatr Nephrol* 2009;24(9):1621–32. With permission.)

animal studies that an initial critical reduction in renal mass will ultimately lead to progressive deterioration of renal function in the remaining renal tissue. CAKUT has been associated with oligonephronia of the contralateral kidney, especially accompanied by VUR.[19]

Hershkovitz et al. found that chronic hypertension and renal disease have been associated in low-birth-weight (LBW) infants, primarily due to prematurity and intrauteral growth restriction (IUGR).[32] Although many LBW infants catch up in growth, their kidneys, due to impaired and incomplete renal growth from IUGR and prematurity, have a lower than expected nephron number that does not improve with renal growth catch-up. They postulated that lifelong renal maintenance is dependent on the number of renal cell divisions, which in turn depends on normal fetal renal development. The cellular mass of the developing kidney depends on a balance between cell proliferation and apoptosis. Animal models have shown that IUGR is associated with higher levels of renal cellular apoptosis. Additionally, the renin–angiotensin system was found to be downregulated in the animal models studied. The authors also found that lower renal donor nephron mass increased the risk of the transplant recipient developing hypertension and transplant loss. Adults with a history of LBW and catch-up renal growth had a higher association of developing hypertension and renal disease.

CHAPTER 21

Renal Anomalies

Gino J. Vricella, Douglas E. Coplen, Paul F. Austin, and Elizabeth B. Roth

INTRODUCTION

Congenital anomalies of the upper urinary tract comprise a diverse group of abnormalities and may be the result of an arrest in development or a malformation. These diverse entities are among the most common malformations in newborns. Using real-time ultrasonography (US) as a screening test in nearly 18,000 healthy infants, Calulo et al. found that nearly 1% had some type of a congenital anomaly of the kidney and urinary tract (CAKUT), and one-quarter of these required surgical intervention.[1] In a similar study of 5700 Asian infants that were screened over a 7-year period, nearly 200 cases (3.5%) of CAKUT were identified.[2] A complete understanding of the embryologic development of the genitourinary tract is a prerequisite for the evaluation of a child with a suspected anomaly.

EMBRYOLOGY

There are three stages in the formation of the nephric system: the pronephros, the mesonephros, and the metanephros. Embryologically, all three kidneys develop from the intermediate mesoderm. The two intermediate stages are the pronephros, which completely disappears, and the mesonephros. Although the mesonephros undergoes degeneration, its duct persists and extends caudally to communicate with the anterior cloaca. As the ducts fuse with the cloaca, canalization progresses both cranially and caudally, with the cranial extent transforming the solid tissue condensations into the definitive nephric ducts with excretory capability. Vestigial remnants of the mesonephric tubules occur in both sexes and are associated with the reproductive tract. In males, some of the mesonephric tubules become the efferent ductules of the testes. The epididymis and vas deferens are also formed from the mesonephric (i.e., Wolffian) ducts. In females, remnants of the mesonephric ducts form vestigial mesosalpingeal structures called epoophoron and paroophoron.

Early in the fourth to fifth weeks, the ureteral bud begins to develop from the distal end of the mesonephric duct near its junction with the cloaca. The cranial end of the ureter then ascends to meet the condensing blastema of the metanephric mesenchyme in the sacral region. This begins to develop into the metanephros and continues its cephalad migration. The cranial end of the ureteral bud begins a series of branchings to form the renal pelvis, the calyces, and a portion of the collecting ducts. This branching is associated with the simultaneous differentiation of the metanephrogenic cap, which becomes arranged around the branching collecting ducts, giving the metanephros a lobulated appearance. The nephron, which consists of the glomerulus, proximal tubule, loop of Henle, and distal tubule, derives from the metanephric mesenchyme. The collecting system, consisting of the collecting ducts, calyces, pelvis, and ureter, is formed from the ureteric bud.

The ascent of the kidneys occurs in part due to true migration and also secondary to differential somatic growth of the lumbar portion of the body. They reach their final level by the end of the eighth week of fetal life. The kidney also undergoes axial rotation medially of 90° during the seventh and eighth weeks before it assumes its final position. During ascent, each kidney receives its blood supply from the neighboring vessels. Initially, this is from the middle sacral artery, then the common iliac and inferior mesenteric arteries, and finally the aorta.

ANOMALIES IN NUMBER

Supernumerary Kidney

A supernumerary kidney is an uncommon anomaly, with less than 100 cases reported in the literature.[3,4] The embryologic basis shares some similarities with that found in ureteral duplication. There are either two ureteral buds arising from the mesonephric duct, leading to double ureters, or a branching of the ureteral bud, which results in a bifid collecting system. Either the two ureteral buds then join two separate metanephroi, or a splitting of the nephrogenic blastema occurs. This later develops into twin metanephroi after induction by the two ureteral buds.

The supernumerary kidney is caudal to the ipsilateral kidney in 60% of cases. A supernumerary kidney associated with complete ureteral duplication is more likely to be in a cranial location. There is generally one extra kidney, but as many as five separate renal masses have been reported. This anomaly occurs more frequently on the left side. The ureter of the anomalous kidney joins the ipsilateral ureter about as commonly as it enters the bladder separately, but only rarely is the ureter ectopic. The extra kidney has its own renal capsule and blood supply. The supernumerary kidney is often smaller, and one-third exhibit other pathologic changes (e.g., hydronephrosis and pyelonephritis). Renal function is frequently decreased in the smaller hypoplastic unit.

Most cases are diagnosed after the third decade of life. Presenting complaints are usually related to urinary obstruction or infection and include pain, fever, or an abdominal mass.[5] However, many patients remain asymptomatic throughout life, and 20% of reported cases were discovered at autopsy.[6] The diagnosis can be readily established via the use of nuclear renal scintigraphy, which will confirm the presence of functioning renal tissue.

Unilateral Renal Agenesis

Renal agenesis, whether unilateral or bilateral, results from a failure of the ureteral bud to induce the metanephric blastema. This could result from agenesis of the ureteral bud, failure of the bud to reach the blastema, absence or abnormality of the metanephric blastema, or failure of the ureteral bud to invade the metanephric blastema.[7] The etiology is most likely secondary to an abnormality with the ureteral bud, as opposed to the metanephric blastema, as the ipsilateral gonad—derived from adjacent mesenchymal tissue—is rarely affected. The high incidence of absent or malformed proximal Wolffian duct (WD) structures in the male and anomalies of the Müllerian duct (MD) structures in the female suggest that the embryologic insult affects the ureteral bud primarily in its early development.

It is unclear whether there is a genetic predisposition or if it is related to other prenatal factors. Parikh et al. found that diabetes and black maternal race were associated with an increased incidence of renal agenesis, but it is probably multifactorial, with both environmental and genetic factors playing a role.[8] A familial tendency has been reported, supporting the latter.[9] The reported incidence of this condition varies between series of patients collected from either clinical or autopsy data. Doroshow and Abeshouse estimated that unilateral renal agenesis (URA) is found in 1 of every 1100 autopsies.[10] The clinical incidence on imaging studies is 1 in 1500, suggesting that most cases are diagnosed during life.[11] Currently, most renal anomalies seen by pediatric urologists are detected prenatally, and URA is no exception, but fetal US studies have detected renal agenesis with a much lower frequency.[12,13] A number of patients previously reported with URA most likely had prior involution of multicystic or dysplastic kidneys. This has been documented to occur prenatally, and rapid involution of multicystic and dysplastic renal units has also been shown to occur early in postnatal life.[14–16] Hiraoka et al. have suggested that aplasia is the predominant cause of congenital solitary kidneys.[17] The presence of the splenic flexure of the colon in an orthotopic location would suggest the prior presence of a renal unit that has since involuted. There is a slight male predominance, and the condition occurs more frequently on the left side. This male predominance may reflect the earlier differentiation of the WD that takes place close to the time of ureteral bud formation. The ureteral bud is more likely to be influenced by abnormalities of the WD than those of the MD, which occurs later.

Associated Anomalies

The ipsilateral ureter is absent in approximately two-thirds of cases.[18] On cystoscopic examination, a hemitrigone will be present in patients with complete ureteral agenesis. This finding has been substantiated with cell lineage studies demonstrating that the trigone has a urogenital sinus origin and should form normally.[19] Anomalies of the contralateral ureter are common, with vesicoureteral reflux (VUR) the most frequent finding (~30%), followed by ureteropelvic (~11%) and ureterovesical (~7%) junction obstruction.[20–22] Although the ipsilateral adrenal gland may have a unique configuration, it is rarely absent (~8%) based on autopsy studies.[18] This is not surprising given the distinct embryological origins of the kidney and adrenal gland.

Genital anomalies, especially in the female, are much more frequently observed. Likewise, patients with known genital anomalies have an increased incidence of renal anomalies.[23] Regardless of sex, both gonads are usually normal. A variety of anomalies may result in the female from incomplete MD formation because of alterations in normal WD development. Approximately 30% of women with URA have an abnormality relating to WD development.[24] Most of the genital anomalies in female patients with URA are asymptomatic, but such anomalies often assume greater clinical importance, leading to earlier evaluation and diagnosis of the absent kidney. The most common problems involve the uterus and vagina. There is often a unicornuate or bicornuate uterus, and the ipsilateral horn and fallopian tube may be rudimentary or absent[25] (Figure 21.2). The fimbriated end of the fallopian tube, however, is usually fully formed and is analogous to the head of the epididymis in the male. A duplex uterus is attributable to a developmental anomaly of the urogenital septum, resulting in incomplete midline fusion of the MDs and a longitudinal vaginal septum. The development of the MD appears to be inhibited by the defective WD if the defect occurs early in development.[26] Defects of the ureteral bud that occur after MD fusion will affect only ureteral and renal development.[27] Obstruction of the lower genital tract can occur, leading to hydrocolpos or hematocolpos. In fact, Smith and Laufer have suggested the acronym OHVIRA to classify the syndrome of obstructed hemivagina and ipsilateral renal anomaly.[28] Patients present with a pelvic mass and/or pain and fail to menstruate at puberty.[29] Patients with complete Müllerian arrest will require vaginal construction to achieve adequate sexual function but will obviously be infertile. Complete absence or hypoplasia of the vagina, the Mayer–Rokitansky–Küster–Hauser syndrome, is frequently associated with agenesis of the kidney and occurs in approximately 1 in 5000 live female births.[30] This syndrome includes not only renal anomalies but also genital tract anomalies, ranging from upper vaginal atresia to total Müllerian agenesis in an otherwise phenotypically normal female with a normal 46,XX karyotype.

The testis and head of the epididymis, which are derived from the mesonephric tubules, are invariably present. All structures proximal to that point, which develop from the WD (the body and tail of the epididymis, vas deferens, seminal vesicle, ampulla, and ejaculatory duct), are absent in 50% of males with URA.[31] Conversely, in those patients presenting with an absent vas, the reported incidence of renal agenesis varies greatly. Donahue and Fauver found an absent kidney in 22/26 (85%) patients with an absent

vas deferens.[32] Goldstein and Schlossberg used computed tomography (CT) to evaluate 26 men with an absence of the vas deferens.[33] URA was noted in only four men, in all of whom the seminal vesicle was absent. Schlegel et al. found an 11% incidence of renal agenesis in infertile men with unilateral agenesis of the vas.[34] Nevertheless, in males the diagnosis of URA should be suspected during a physical examination when the vas deferens or body and tail of the epididymis are impalpable. This may be more common in adults undergoing evaluation for infertility. In infants and young boys, URA should be considered when vasal and/or epididymal anomalies are incidentally found at the time of orchiopexy.

Approximately 25%–40% of patients with URA have anomalies of other organ systems. The most frequently affected are the cardiovascular (30%), gastrointestinal (25%), and musculoskeletal (14%) systems.[35] URA is associated with several syndromes, including Turner's, Poland's,[36] Goldenhar's,[37] VACTERL association[38] and Klippel–Feil.[39]

Diagnosis and Imaging

There are no specific symptoms that suggest an absent kidney. Previously, most reports were compiled from autopsy series, but now prenatal screening is detecting URA. It has long been held that hypertrophy of the solitary kidney occurs as an adaptive compensatory response, and this has been demonstrated to occur in utero.[40] This is somewhat curious given the fact that the placenta is almost entirely responsible for filtration of blood and elimination of waste products during gestation. In any event, URA may be suspected by a number of radiological manifestations. US, radionuclide scintigraphy, and MRI have completely replaced arteriography in diagnosing URA. A plain film of the abdomen will often demonstrate that the gas pattern of the splenic or hepatic flexure of the colon is displaced into the renal fossa.[41,42] A retroperitoneal ultrasonogram with color Doppler will show the absence of the kidney and ipsilateral renal vessels. The diagnosis of URA can usually be confirmed with a dimercaptosuccinic acid (DMSA) scan showing absent uptake of the isotope on one side, with the contralateral kidney often showing compensatory hypertrophy.[43] A DMSA scan will also detect an ectopic (usually pelvic) or a crossed ectopic kidney in cases where the nonvisualized orthotopic kidney is thought to be absent.[44]

Historically, when a diagnosis of URA was confirmed, voiding cystourethrogram was recommended because of the nearly 30% incidence of contralateral reflux. Given the evolving paradigm in the diagnosis, treatment, and clinical significance of VUR, this once certain recommendation is somewhat debatable, especially in the absence of a contralateral renal anomaly on ultrasonographic and/or renal scintographic imaging. US and MRI are useful for examining the internal genital structures in females with a diagnosis of renal agenesis. In general, the uterus and cervix can be visualized in both infants and older girls. Renal sonography has been recommended for the screening of parents and siblings of children born with renal agenesis. Roodhooft et al. reported a 9% incidence of asymptomatic renal malformations in family members, with URA being the most common finding.[45]

Prognosis

There are both experimental and clinical studies suggesting that hyperfiltration of remnant nephrons may have an adverse effect on renal function, depending on the number of nephrons remaining.[46] There are reports of focal glomerulosclerosis, the renal lesion that develops in hyperfiltration, occurring in humans with URA.[47–49] Some studies have noted an increased rate of hypertension, proteinuria, and mild renal insufficiency.[50,51] However, others have noted normal renal reserve in patients with URA.[52]

There is fairly wide variability in terms of what constitutes a normal number of nephrons in humans. Consequently, it would follow that an individual with fewer functional nephrons would be at greater risk for renal insufficiency at any age, regardless of etiology. Moreover, contemporary evidence would suggest that subtle defects in ureteral bud branching can cause a reduced nephron number, which may lead to renal disease later in life.[53] Recently, Sanna-Cherchi et al. evaluated the long-term functional outcomes in individuals with CAKUT, including those with URA from a single pediatric nephrology center.[54] Somewhat surprisingly, patients with a solitary kidney had a 50% probability of requiring dialysis by 30 years of age. Notably, most of the patients with URA in this study were diagnosed during adolescence and had a normal creatinine level at the time of diagnosis. Interestingly, the patients diagnosed at birth had a slightly elevated creatinine level (0.68 mg/dL). These and other studies point out the fundamental differences in individuals with URA and adults who undergo unilateral nephrectomy. The number of nephrons in children with URA may be abnormally low, and those with fewer nephrons may be at greater risk for developing focal glomerulosclerosis.

From a practical standpoint, most parents will desire counseling on any dietary or activity restrictions for their child. The American Academy of Pediatrics recommends a "qualified yes" for participation by athletes with single kidneys in contact sports. In a recent study, Grinsell and colleagues reviewed data from the National Athletic Trainers' Association High School Injury Surveillance Study from 1995 to 1997.[55] Researchers analyzed data from more than 4.4 million "athlete exposures," defined as one athlete participating in one game or practice. Of 23,666 reported injuries, only 18 involved a kidney, and none of those were catastrophic or required surgery. The authors concluded that the data do not support limiting sports participation by athletes with otherwise normal single kidneys.

There is a paucity of evidence-based data to guide the management of patients with a single kidney who might be identified as at risk of progressive renal damage. A sensible approach to lifestyle factors that promote healthy living, such as avoiding obesity, smoking, and a high-salt diet, is essential, as they are likely to have adverse effects on renal hemodynamics and contribute to progression of chronic kidney disease (CKD)[56–58] in these nephron-deficient individuals. Additionally, it is known that obese individuals are more likely to develop proteinuria and CKD following unilateral nephrectomy.[59] Current suggestions for children with a normal-appearing single kidney include annual assessments of blood pressure and urinalysis for

proteinuria, the hallmarks of a progressive decrease in glomerular filtration rate.[60] Periodic laboratory evaluation of blood urea nitrogen and serum creatinine levels can be performed. Should there be hypertension, proteinuria, and/or impaired renal function, pediatric nephrology consultation should be obtained. The available options for attenuating the progression of CKD include dietary protein restriction,[61] control of proteinuria,[62] and optimum management of hypertension and hyperlipidemia, including therapy with angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers.[63]

Bilateral Renal Agenesis

Prior to the widespread use of prenatal US and the availability of legalized pregnancy termination in the United States, the incidence of bilateral renal agenesis (BRA) was about 1 in 4000 births with a male–female ratio of 2.5:1.[64] As stated previously, renal agenesis occurs when the ureteric bud fails to develop and thus fails to induce differentiation of the metanephric mesenchyme to renal tubular epithelium. In vitro models reveal that when the ureteric bud and metanephric mesenchyme meet, the ureteric bud branches and nephrons form within 3–7 days of culture; however, if they remain apart, nephrons do not form and the mesenchymal tissue undergoes apoptosis.[65]

BRA has been associated with a maternal body mass index of greater than 30 kg/m^2 prior to pregnancy (adjusted odds ratio [OR] = 1.92, 95% confidence interval [CI] 1.00–3.67), smoking during the periconceptional period (OR = 2.09, 95% CI 1.08–4.03), and binge drinking during the second month of pregnancy (OR = 3.64, 95% CI 1.19–11.1).[66] Advanced maternal age also appears to be a risk factor.[67]

Potter syndrome is a historical term that was used to define the typical appearance of a fetus or neonate exposed to severely decreased or absent amniotic fluid secondary to renal disease. Typically, this syndrome is characterized at birth by pulmonary hypoplasia, limb deformations (altered positioning of hands and feet, clubbed feet, and hip dislocation), and flattened facies. The most consistent finding is a prominent epicanthal fold that extends onto the cheek. The skin of these infants is very loose, particularly over the hands. It results from external compression of the fetus, limitation of fetal movement, and alteration in the dynamics of lung liquid movement due to severe oligohydramnios. Potter syndrome can also be seen in infants with normal kidneys with prolonged leakage of amniotic fluid or rarely with severe fetal growth restriction; thus, it is not pathognomonic of renal anomalies per se (Figure 21.3).

The diagnosis of BRA is based on sonographic nonvisualization of the fetal kidneys, ureters, and bladder, accompanied by oligohydramnios. The major nonspecific marker of BRA is severely reduced or absent amniotic fluid. In early pregnancy, the movement of fluid across the amnion, fetal membranes, and chorionic plate is thought to be the dominant source of amniotic fluid. Fetal urine becomes the main source after about 16 weeks of gestation. Therefore, amniotic fluid volume in pregnancies complicated by renal agenesis might appear normal in early pregnancy (i.e., prior to 16 weeks), even though sharply reduced or absent amniotic fluid volume is the most prominent ultrasonic feature of this disorder by the midtrimester.[68] The fetal kidneys and adrenal glands can be visualized by transabdominal US between the 12th and 15th weeks of gestation, with the prenatal detection rate for BRA reported to be between 84% and 91%.[69]

Interestingly, when siblings and parents of an index child with BRA were screened, 4.5% had URA, which is 1000-fold higher than the general population.[45,70] Recently, McPherson evaluated renal anomalies in families of individuals with congenital solitary kidneys that included renal agenesis or dysplasia or hypoplasia. The empiric risk was 7% for offspring, 4% for parents, and 2.5% for siblings. It was noted that this may be an underestimation, because not all relatives underwent US screening. The incidence of BRA in offspring of congenital solitary kidney probands was about 1%, which is significantly greater than the risk found in the general population but less than that for families with a history of BRA. This has led to the recommendation that for parents and siblings of infants born with either unilateral or BRA or dysgenesis, retroperitoneal US screening be performed to evaluate for renal anomalies.[45,71]

BRA is associated with other structural abnormalities in more than 50% of cases. The types of structural anomalies are similar to those in patients with congenital solitary kidney, although the frequency is lower. These abnormalities include a variety of syndromes associated with chromosomal anomalies, caudal dysgenesis, VACTERL (vertebral anomalies, anal atresia, cardiac defects, TE [tracheoesophageal] fistula, renal defects, limb defects), and isolated anomalies of the cardiovascular, skeletal, and central nervous systems.[71]

BRA is incompatible with extrauterine life because prolonged absence of amniotic fluid results in pulmonary hypoplasia, leading to severe respiratory insufficiency at birth. Fetuses are able to survive in utero since the placenta is responsible for fetal oxygenation and excretion of wastes; however, there is a higher rate of fetal loss that is probably related to cord compression. As many as 33% of fetuses with BRA die in utero, and approximately 40% of such infants are stillborn.[72] This poor prognosis has led to the recommendation of termination of the pregnancy if the diagnosis is made early in gestation.

ANOMALIES OF ROTATION

Abnormal rotation, or malrotation, is most commonly associated with an ectopic or fused kidney, but may also occur in kidneys that complete their ascent. As the normal maturing kidney assumes its final position in the renal fossa, it is oriented such that the calyces point laterally and the pelvis faces medially (Figure 21.1). The true incidence of this type of anomaly is probably understated because in many patients there are no clinical manifestations. Campbell reported only 17 cases of renal malrotation among 32,834 autopsies on adults.[73] Smith and Orkin found an incidence of 1 in 390 hospital admissions and stated that malrotation accounts for 10% of upper urinary tract anomalies.[74]

It is thought that medial rotation of the collecting system occurs simultaneously with renal migration. The

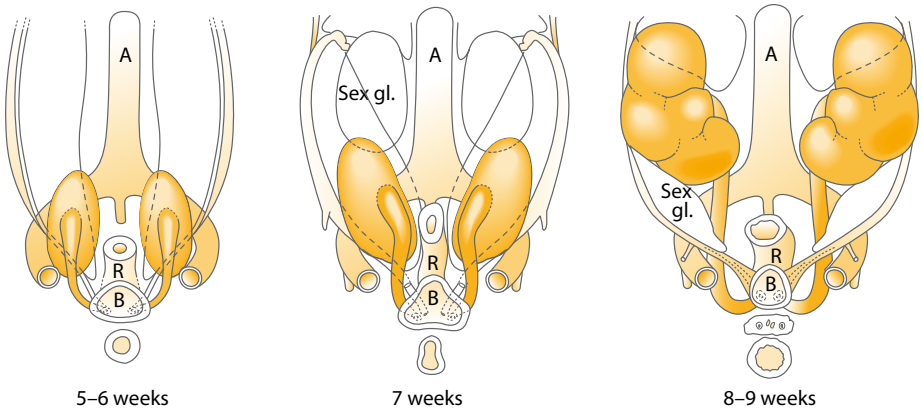

FIGURE 21.1 Ascent and rotation of kidneys during fetal life. The normal rotation of the kidney from facing forward to facing medially is shown. A, aorta; R, rectum; B, bladder; Sex gl, sex gland. (Adapted from Campbell MF. *Clinical Pediatric Urology*. Philadelphia: WB Saunders, 1951.)

kidney starts to turn during week 6, and it completes this process by rotating 90° toward the midline by the time ascent is complete at the end of the ninth week of gestation. The rotation of the fetal kidney has been proposed to be the result of differential growth, with more tubules being formed on the ventrolateral side than on the dorsomedial side.[75] This theory does not explain all the abnormalities of rotation. Weyrauch suggested that the ureteral bud makes more lateral contact with the renal blastema.[76] This may explain an anomalous initial position of the kidney, but does not explain normal renal rotation.

The different types of malrotation are depicted in Figure 21.4. The most common is an incomplete rotation, or nonrotation (Figure 21.5). The renal pelvis is anterior or between the fetal anterior and normal medial position in the adult. Other major types of anomalous rotation are reverse rotation and hyperrotation (excessive rotation), in which the kidney faces laterally, but these are rare (Figure 21.6). In reverse rotation, the renal pelvis rotates laterally and the renal vessels cross the kidney anteriorly to reach the hilum (Figure 21.7). In excessive rotation, the kidney rotates more than 180° but less than 360°. The pelvis faces laterally, but the renal vessels are carried posteriorly to the kidney. Less severe hyperrotation may leave the renal pelvis in a dorsal position. The renal blood supply does not appear to be the cause or a limiting factor in malrotation, but rather follows the course of renal nonrotation, hyperrotation, or reverse rotation.

Malrotation is usually discovered incidentally during imaging of the kidney. When symptoms occur, they are most often related to upper urinary tract obstruction and can be in the form of abdominal or flank pain, nausea, and/or emesis. Hematuria associated with hydronephrosis, infection, and calculus formation may also occur

FIGURE 21.6 CT demonstrating excessive rotation of the right kidney.

secondary to poor urinary drainage. Obstruction may be secondary to compression of the ureter from an anomalous accessory vessel or other obstructive lesions that also occur in normally rotated kidneys (e.g., calculus). The calices are often distorted, even without any associated obstruction. Axial imaging, such as CT or MRI, can be very informative. The upper third of the ureter may be displaced laterally and the renal pelvis may appear elongated, suggesting obstruction or effacement by an extrinsic mass. Treatment of malrotation is reserved for alleviation of associated obstruction, calculi, or infection secondary to poor drainage.

ANOMALIES OF ASCENT

Renal ectopia (Greek: *ek* ["out"] and *topos* ["place"]) is the term used to describe a kidney that lies outside the renal fossa. The kidney migrates cephalad early in gestation to reach its normal position. Failure of ascent can be due to a number of factors: abnormality of the ureteral bud or metanephric blastema, genetic abnormalities, teratogenic causes, or anomalous vasculature acting as a

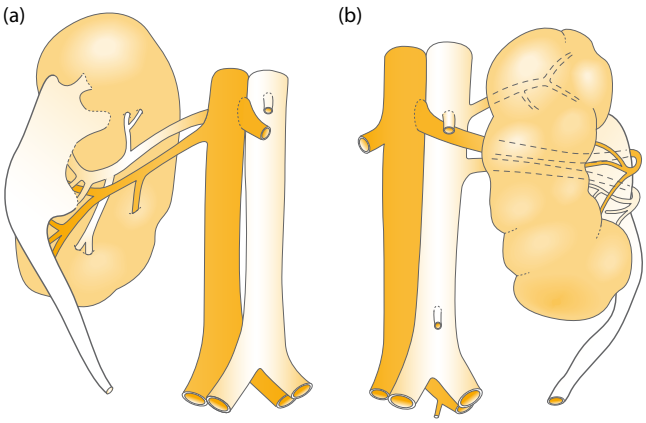

FIGURE 21.7 Abnormal renal rotation: (a) reverse rotation; (b) hyper-rotation. (Adapted from Weyrauch HM Jr. *Surg Gynecol Obstet* 1939;69:183–99.)

barrier to ascent.[77] During ascent, the kidney receives its blood supply from the middle sacral artery, iliac artery, and finally, the aorta. The anomalous blood supply that is invariably present is dependent on the final position of the kidney and is not believed to be the cause of the malposition. However, the blood vessels are frequently short, rendering surgical mobilization very difficult.

Incidence

The incidence of renal ectopia in postmortem studies varies from 1 in 500 to 1 in 1290.[78,79] The incidence is historically higher in autopsy series than in clinical studies, suggesting that many cases remain unrecognized throughout life.[77] With increasing clinical detection, however, the incidence among hospitalized patients has approached the autopsy rate of about 1 in 900.[80] There is a slight predilection for the left side, and 10% of cases are bilateral. Simple renal ectopia refers to a kidney that remains in the ipsilateral retroperitoneal space. This is in contradistinction to renal ptosis, in which the kidney initially is located in its proper place (and has normal vascularity) but moves downward in relation to body position. The differentiation between a ptotic kidney and renal ectopia can be difficult, but there are several discerning features. The length of the ureter may be helpful. In renal ectopia, ureteral length corresponds to the location of the kidney; in a ptotic kidney, the ureter appears redundant. The ptotic kidney is mobile and usually can be manipulated into its normal position. The most common position for simple ectopia is in the pelvis (sacral or pelvic kidney) opposite the sacrum or below the aortic bifurcation.[79] The lumbar or iliac ectopic kidney is one that is fixed above the crest of the ileum but below the level of L-2 and L-3. Other positions are abdominal, thoracic, and crossed. Crossed renal ectopia refers to a kidney positioned contralateral to the side in which its ureter inserts into the bladder (see discussion on anomalies of fusion later in this chapter). Lastly, malrotation often accompanies renal ectopia (Figure 21.8).

FIGURE 21.8 Malrotated ectopic kidney opposite lower lumbar vertebrae.

Diagnosis

With the increasing use of various imaging modalities, the incidence of an asymptomatic ectopic kidney is increasing. The infrequent cases of symptomatic renal ectopia diagnosed in childhood present with symptoms attributed to the genitourinary or gastrointestinal system, such as vague abdominal pain or renal colic secondary to ureteral obstruction (e.g., ureteropelvic junction [UPJ] obstruction or urolithiasis). The abnormal position of the kidney results in a pattern of direct and referred pain that is atypical for colic and may be misdiagnosed as acute appendicitis or as pelvic inflammatory disease in female patients. Urinary tract infection is the presentation in about 30% of children. The ectopic kidney may also be noted incidentally, most frequently on prenatal US. A pelvic kidney is the most common finding in a fetus with an empty renal fossa and normal amniotic fluid volume.[81]

Historically, pelvic kidneys were often difficult to recognize on excretory urography because they overlie the bony pelvis, which obscures the collecting system and can lead to a misdiagnosis (Figure 21.9). However, most can be now be identified by US or radionuclide imaging.[82] Whenever a kidney is absent on US, radionuclide imaging is indicated to exclude an ectopic kidney. However, if the kidney is totally nonfunctional, a CT scan or MRI may be the best method of localization.[83] If cystoscopy is performed, the ureteral orifices are invariably normal (unless the ureteral orifice is also ectopic). If surgery is indicated on an ectopic kidney, retrograde pyelography can be used to delineate the collecting system anatomy (Figure 21.10). Magnetic resonance arteriography can also be performed preoperatively to define the anatomy of the renal vasculature, which is especially important in cases of solitary ectopia.

Hydronephrosis is frequently noted in ectopic kidneys. Gleason et al. found that half of the dilatation could be attributed to UPJ or ureterovesical junction (UVJ) obstruction.[84] Obstruction in the ectopic kidney is frequently due to a high insertion of the ureter on the renal pelvis (Figure 21.11). High-grade reflux was responsible for 26% of hydronephrotic kidneys, and the extrarenal collecting system with malrotation accounted for the remainder. Diuretic renography may be helpful to distinguish these abnormal pyelocaliceal patterns from UPJ obstruction. The ectopic kidney can be clearly shown on the renal scan, but the gamma camera should be placed anteriorly to obtain better images (Figure 21.12).

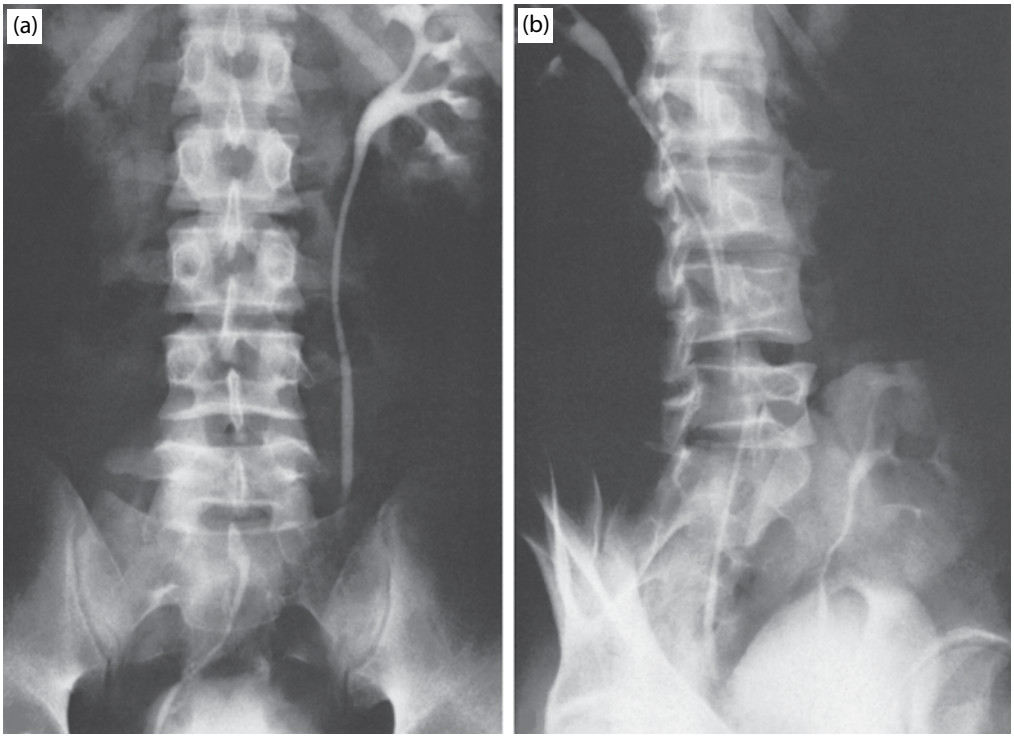

FIGURE 21.9 Excretory urogram in patient with a right pelvic kidney. (a) The short right ureter is seen overlying the bony structures. (b) Oblique film allows much better visualization of the collecting system and renal outline.

Associated anomalies

The contralateral kidney is abnormal in up to one-half of patients.[77] There is a 10% incidence of contralateral renal agenesis. Associated VUR is found in 70%–85% of children with an ectopic kidney.[85] The adrenal gland is invariably orthotopic. Genital anomalies are common, with an incidence ranging from 10% in males to 75% in females.[86] In males, the most common abnormalities are hypospadias and undescended testes.[85] Anomalies of the reproductive organs in the female include duplication of the vagina, bicornuate uterus and hypoplasia or agenesis of the uterus or vagina.[87,88] These may become clinically important during pregnancy and may require cesarean section.[86] Anomalies of other organ systems also occur with increased frequency. Skeletal anomalies are present in up to 50% of children. The most common include asymmetry of the skull, rib abnormalities, dysplastic vertebrae, and absent bones. Cardiovascular lesions were noted in 9 of the 21 children, and gastrointestinal abnormalities were found in one-third of patients in one study.[77] Others, however, have reported a lower incidence of associated extragenitourinary anomalies.[86]

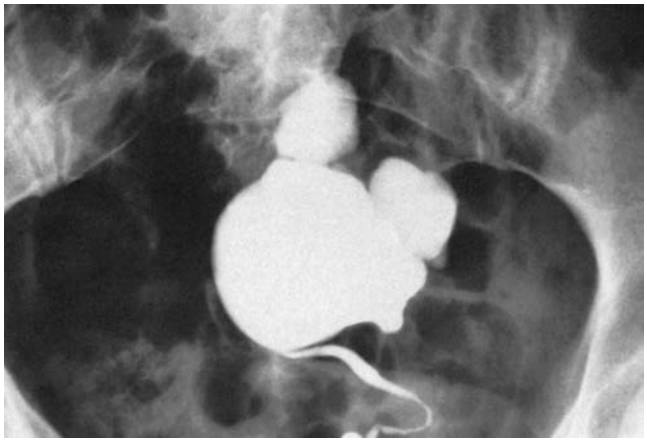

FIGURE 21.10 Retrograde pyelogram in a patient with a symptomatic ureteropelvic junction obstruction in a left pelvic kidney.

Management

Overall, renal disease will develop in 40% of patients with a solitary pelvic kidney, with the most common problem being a UPJ obstruction.[84,86] This may be due to the malrotation and high ureteral insertion, or an anomalous vessel that partially obstructs the collecting system. Obviously, treatment must be individualized. Most cases have traditionally been managed via a transabdominal approach for pyeloplasty; however, laparoscopy is increasingly being utilized in these cases.[89,90] The goal of surgery is to achieve dependent drainage, and in some cases, ureterocalicostomy may be best. Endopyelotomy has been used in a small number of selected patients with reasonable success.[91] Renal stones may develop in these kidneys from either infections or sluggish drainage (Figure 21.13). Historically, these were managed with open removal, but contemporary literature would suggest that pyelolithotomy is amenable to a laparoscopic approach.[92] Minimally invasive endourologic techniques, such as percutaneous

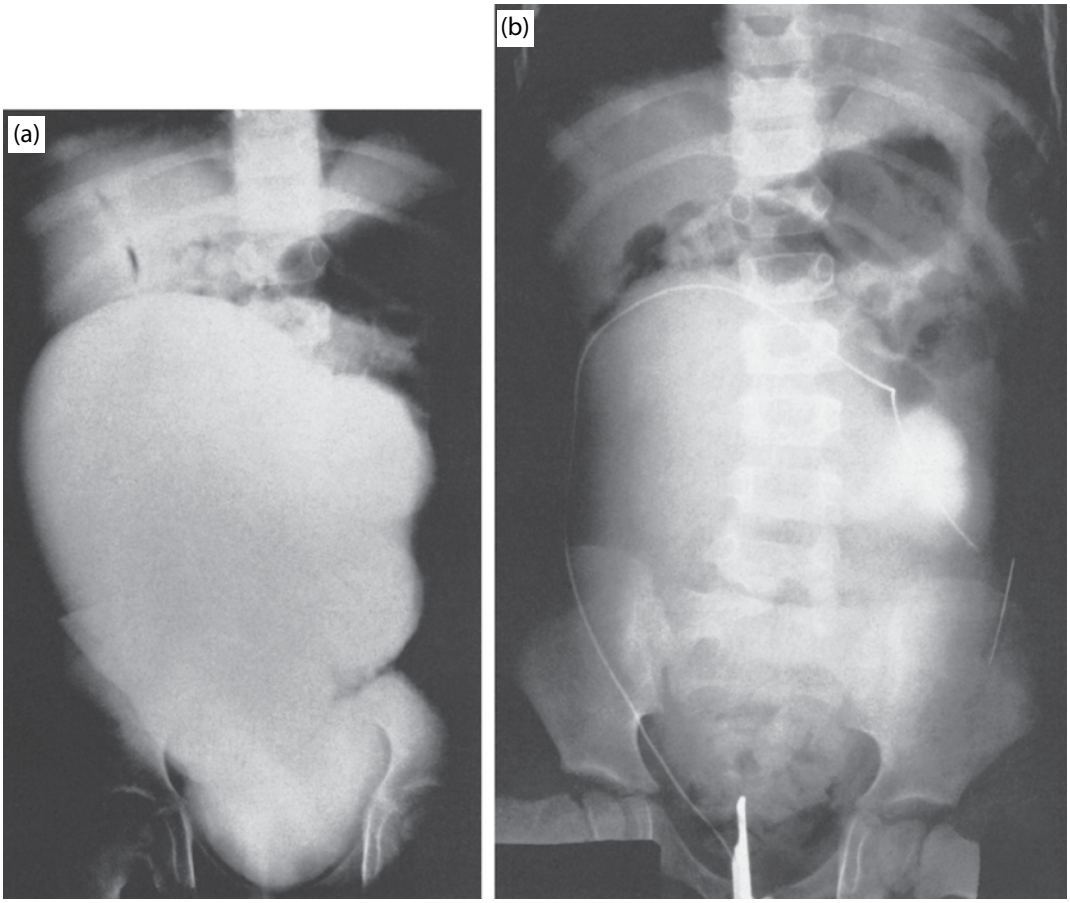

FIGURE 21.11 Ectopic solitary pelvic kidney in a 6-year-old boy with gross hematuria. (a) Excretory urogram showing giant hydronephrosis. (b) Retrograde pyelogram showing a catheter in the ureter with high insertion into pelvis.

nephrolithotomy, extracorporeal shock wave lithotripsy, and ureteroscopy, can also be utilized, particularly if the ureter is dependent in position. An important consideration in management is that the contralateral kidney is commonly abnormal, so that every effort should be made to preserve renal parenchyma.

Thoracic Kidney

The rarest form of renal ectopia exists when the kidney is positioned considerably higher than normal. Excessive cranial migration of the kidney results in a thoracic kidney. N'Guessan et al. prefer to call this a "superior ectopic kidney" because most high kidneys actually lie below the diaphragm.[93] Intrathoracic ectopia denotes either a partial or a complete protrusion of the kidney above the level of the diaphragm into the posterior mediastinum. This accounts for less than 5% of cases, with an incidence of 1 in 13,000 autopsies, with more than 140 cases reported.[78,94] The left side is more commonly involved, and there is a male predominance. The condition is rarely bilateral.[93]

Renal ascent is normally complete by the eighth week of gestation. An intrathoracic kidney may be the result of accelerated ascent prior to diaphragmatic closure or delayed closure of the diaphragmatic anlage, allowing continued ascent.[93] The renal vascular supply often arises from the normal site of origin on the aorta, but may arise more

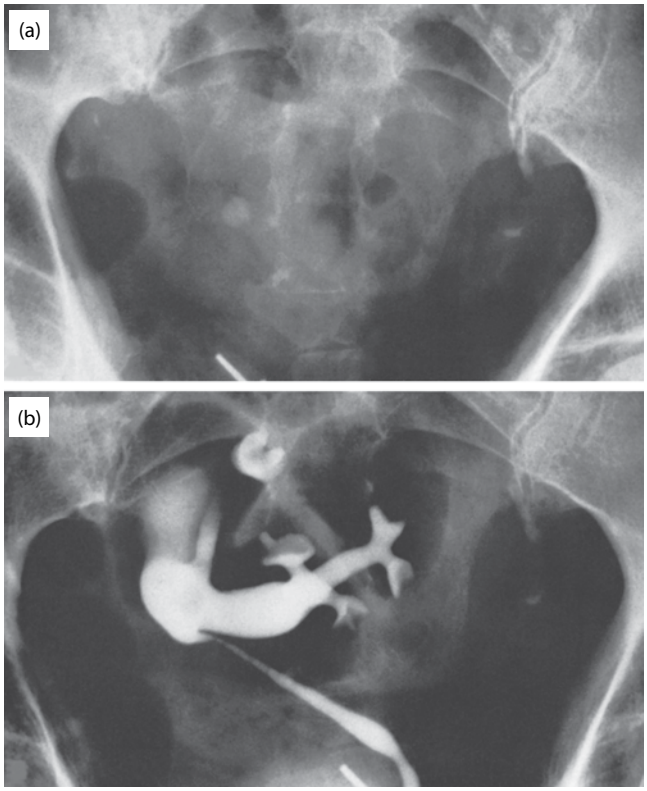

FIGURE 21.13 Left pelvic kidney. (a) Kidney–ureter–bladder (KUB) study revealed opaque calculus in the true pelvis. (b) Retrograde pyelogram confirmed the stone to be within the renal pelvis of the pelvic kidney.

superiorly.[95] The ureter and hilar vessels enter through the foramen of Bochdalek. The adrenal gland frequently remains caudal to the kidney in its normal location.[93] A superior ectopic kidney in association with a Bochdalek's hernia is uncommon. In this circumstance, there is herniation of other viscera through the diaphragm, and the kidney is mobile and can be easily withdrawn from the thorax. The kidney otherwise appears normal and has generally completed rotation.

In general, the thoracic kidneys function normally and most patients are asymptomatic. As with most renal anomalies, prenatal diagnosis is possible and UPJ obstruction has been noted and treated successfully.[94] The condition is most often detected on routine chest radiographs as a suspected mediastinal mass. Contrast-enhanced axial imaging (i.e., CT or MRI) can aid in confirming the diagnosis.

ANOMALIES OF FUSION

The congenital renal anomaly that produces some of the most bizarre-looking and perhaps most interesting urograms is the result of fusion of two or more kidney masses. Because the mechanisms responsible for normal complete ascent of the kidney during gestation are not entirely known, the cause of crossed ectopia and/or fusion remains elusive. There are several proposed mechanisms. The kidneys cross the umbilical arteries as they ascend out of the pelvis. Wilmer suggested that crossover occurs as a result of pressure from abnormally placed umbilical arteries that prevent cephalad migration of the renal unit, which then follows the path of least resistance to the opposite side.[96] Malposition of the umbilical arteries may also cause the developing nephrogenic blastemae to fuse in the midline, resulting in a horseshoe kidney. Alexander et al. theorized that crossed ectopia is a ureteral phenomenon, with the developing ureteric bud wandering to the opposite side and inducing differentiation of the contralateral nephrogenic anlage.[97] Cook and Stephens postulated that crossover is the result of malalignment and abnormal rotation of the caudal end of the developing fetus.[98] Fusion of the metanephric masses may occur when the renal anlagen are still in the true pelvis before or at the start of cephalad migration, or it may occur during the latter stages of ascent. The extent of fusion is determined by the proximity of the developing renal anlagen to one another. After fusion, advancement of the kidneys toward their normal location is impeded by midline retroperitoneal structures (e.g., aortic bifurcation, inferior mesenteric artery, and base of the small bowel mesentery) and malrotation is present in all cases.[99,100] Teratogenic factors and genetics have also been implicated.[101,102]

Horseshoe Kidney

The horseshoe kidney is the most common renal fusion anomaly, with the two renal units joined at their lower poles in more than 90% of cases (Figure 21.14). The isthmus crossing the midline joining the two kidneys consists of either renal parenchyma or fibrous tissue. The horseshoe kidney is usually positioned low in the abdomen, with the isthmus lying just below the junction of the inferior mesenteric artery and aorta. It is postulated that the inferior mesenteric artery obstructs the isthmus and prevents further ascent. Although usually situated anterior to the great vessels, the isthmus may cross posterior to the aorta and/or inferior vena cava.[103]

The reported incidence of horseshoe kidney is approximately 1 in 400, with contemporary radiologic literature quoting an incidence of 1 in 666 individuals.[78,104] The abnormality is more common in males. In autopsy series, this anomaly is found more commonly in children, which is attributed to the high incidence of associated congenital anomalies responsible for their untimely demise.[105] This is in comparison with the 3.5% incidence of associated congenital malformations in adults discovered to have horseshoe kidneys. Horseshoe kidneys have been reported in identical twins and in several siblings within the same family.[106]

Diagnosis

Clinical features from an affected horseshoe kidney are often vague and nonspecific. In the absence of a palpable mass or clinical symptomatology, the anomaly is not suspected until an imaging study is obtained. Prenatal US is now detecting most horseshoe kidneys.[81] The classic features of a horseshoe kidney have been noted on excretory

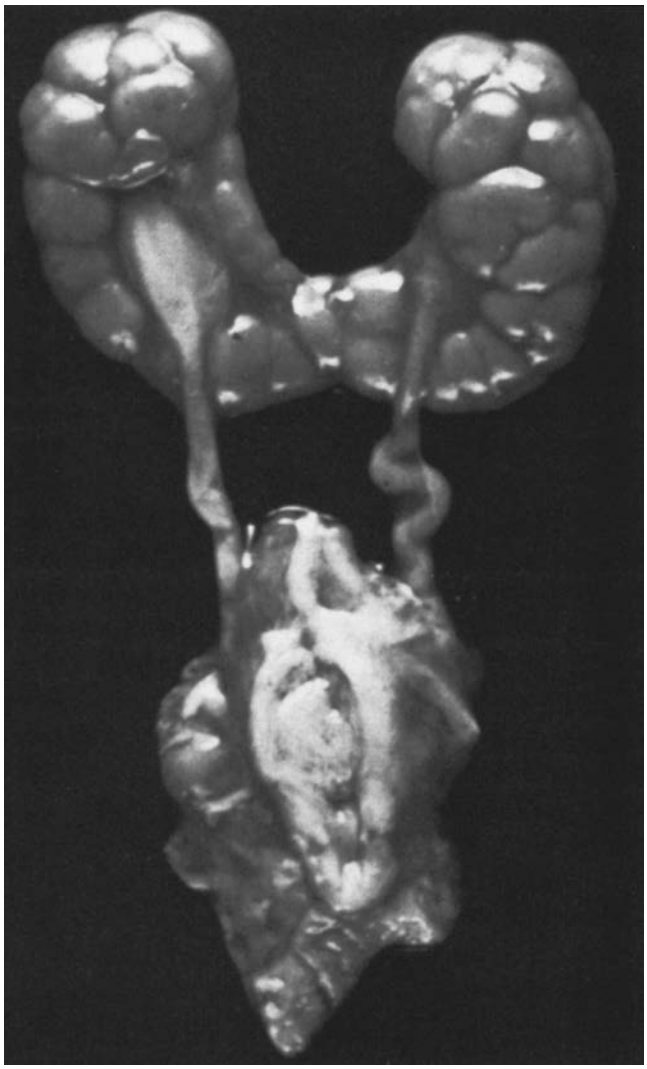

FIGURE 21.14 Horseshoe kidney, postmortem specimen

urography, which is now seldom performed in children (Figure 21.15). Malrotation of the kidney is always present and is attributed to very early fusion of the kidneys before rotation is complete. The renal pelves remain anterior, with the ureters crossing the isthmus. The orientation of the calices is generally anteroposterior, but the lowermost calices invariably point toward the midline, medial to the ureter. The course of the ureters is variable, but they often lie anterior to the pelvis. Other pertinent urographic findings are low-lying kidneys, and the lower outer border of the kidney appears to continue across the midline. The diagnosis of a horseshoe kidney can be confirmed by a variety of imaging techniques, including US, CT, and MRI (Figure 21.16). In general, the fusion of the kidneys can be clearly visualized with any of these studies (Figures 21.17 and 21.18). Previously, renal arteriography was often performed before surgery to delineate the vasculature. In the majority of cases, there are multiple renal vessels. The blood supply to the isthmus is particularly variable and often supplied by a separate vessel. This may arise from the aorta, common iliac, or inferior mesenteric arteries.

Associated Anomalies

There is a frequent association of other anomalies in children with horseshoe kidney, especially when the horseshoe kidney is discovered in the newborn period. Zondek and Zondek examined the postmortem records of 99 individuals with horseshoe kidneys.[107] Infants who were stillborn or who died within the first year of life had a 78% incidence of other malformations. This implies that a horseshoe kidney occurs more often in association with other serious congenital anomalies. The most commonly affected organ systems were the gastrointestinal, skeletal, cardiovascular, and central nervous systems. Boatman et al. reported that one-third of patients with horseshoe kidney had at least one other abnormality.[108]

Several well-known syndromes have a predisposition for horseshoe kidneys. Trisomy 18 is associated with a 21% incidence of renal fusion.[109] More than 60% of patients with Turner's syndrome have renal abnormalities, including horseshoe kidney, ureteral duplication, or other minor abnormalities.[110] One study noted a 15% prevalence of horseshoe kidney in females with Turner's syndrome.[111] There is also an increased incidence of horseshoe kidney in patients with neural tube defects.[112] Other genitourinary abnormalities are also encountered with increased frequency, including 10% of patients who have ureteral duplication, and up to 80% of children who undergo evaluation are found to have VUR.[113] A more recent report by Cascio et al. found VUR in 13/40 patients with horseshoe kidney undergoing cystography.[114] Multicystic dysplasia[115] and autosomal dominant polycystic kidney disease have also been reported.[116] Hypospadias and undescended testes occur in 4% of the males, and bicornuate uterus or septate vagina in 7% of females.[108] Retrocaval ureter has been found in association with a horseshoe kidney in six patients.[117]

Prognosis

A horseshoe kidney, in and of itself, is not thought to affect life expectancy. Nearly one-third of patients with a horseshoe kidney remain undiagnosed throughout life.[116] In fact, Glenn observed patients with horseshoe kidneys for an average of 10 years after discovery and found that almost 60% of these remained asymptomatic.[118] Only 13% had persistent urinary infection or pain, and 17% developed recurrent calculi. Most women are able to progress through pregnancy and delivery without adverse effects because a horseshoe kidney is located above the pelvic inlet.[119] In those patients with problems, symptoms are most often secondary to hydronephrosis, UTI, or urolithiasis. These patients generally present with vague abdominal pain. Patients can develop abdominal pain and nausea, with hyperextension of the spine (Rovsing syndrome), presumably resulting from stretching of the isthmus. Operations to divide the isthmus were once performed to relieve pain, but this procedure has largely been abandoned, as it has been demonstrated to have little merit.[116,118]

UPJ obstruction is the most common cause of hydronephrosis, occurring in approximately one-third of patients diagnosed in their lifetime. Kao et al. performed diuretic renography in 22 children with a horseshoe kidney detected on routine screening.[120] Only 1 of 44 renal units (2.3%) was found to have obstructive hydronephrosis. This suggests that most cases of obstruction are acquired over time, by either a high ureteral insertion or an anomalous renal vessel. It must be recognized that the calices may have an abnormal appearance as a result of the malrotation alone, and that not all these kidneys are obstructed. Kao et al. showed that 25% of renal units had some stasis prior to administration of diuretic.[120] In some children, the upper urinary tract dilatation may be secondary to VUR (Figure 21.19).

The increased risk of urolithiasis is attributed to stasis secondary to hydronephrosis, but metabolic factors should not be overlooked.[121] A recent multicenter study showed that all patients with a horseshoe kidney and calculi had some metabolic abnormality.[122] Hypercalcuria,

FIGURE 21.19 Horseshoe kidney. Voiding cystourethrogram demonstrating high-grade vesicoureteral reflux into the left renal moiety. Note the medial pointing calyx in the lower pole extending into the isthmus.

hypocitraturia, and low urine volumes were the most common defects. When stone disease is present, extracorporeal shock wave lithotripsy, ureteroscopy, and percutaneous nephrolithotomy yield comparable stone-free rates of between 70% and 80%, depending on the definition of success and number of procedures (including ancillary procedures) required to achieve stone-free status.[123–125]

More than 100 cases of renal malignancy have been reported in patients with a horseshoe kidney, with a number of tumors arising from the isthmus.[126,127] There appears to be an increased incidence of renal pelvic tumors and nephroblastoma in patients with horseshoe kidneys compared with the general population.[127,128] It has been suggested that the increased occurrence of chronic infection, obstruction, and stone formation may contribute to the higher than expected incidence of renal pelvic tumors. Renal cell carcinoma accounts for about half of the kidney cancer cases, although the incidence is no greater than that in the general population. Interestingly, Wilms' tumor is the second most common tumor found in horseshoe kidneys. In a review of National Wilms Tumor Study Group (NWTSG) patients, Mesrobian et al. found that there was a sevenfold increased risk of a Wilms' tumor developing in patients with a horseshoe kidney.[129] Neville et al. subsequently updated the NWTSG experience and identified 41 children with Wilms' tumor arising in a horseshoe kidney.[130] Most of these tumors were found on the left side, rarely in the isthmus, and practically all had favorable histology.

FIGURE 21.20 Crossed ectopia, with the right kidney crossing midline and fused to the lower pole of the left kidney.

Crossed Renal Ectopia

Crossed renal ectopia is the second most common fusion anomaly. As stated previously, the mechanisms responsible for renal ascent are not well defined, and therefore the exact cause of crossed renal ectopia remains largely unknown. The ectopic kidney crosses the midline to lie on the opposite side from its ureteral insertion into the bladder (Figure 21.20). The four varieties of crossed renal ectopia are illustrated in Figure 21.21. The incidence of crossed ectopia has been placed at 1 in 7000 autopsies.[80] Crossed renal ectopia with fusion is the most common type and accounts for 85% of the cases. Crossed ectopia without fusion represents fewer than 10% of all cases, and solitary crossed ectopia and bilateral crossed ectopia are exceedingly rare.[131] With all these abnormalities, there is a slight male predominance, and crossing from left to right occurs more frequently than right to left.

McDonald and McClellan described six different varieties of crossed ectopia with fusion (Figure 21.22).[132] The most common form is unilateral fused type with inferior ectopia, in which the upper pole of the crossed kidney is fused to the lower pole of the normally positioned kidney. The renal pelves remain in their anterior position, representing a failure to complete medial

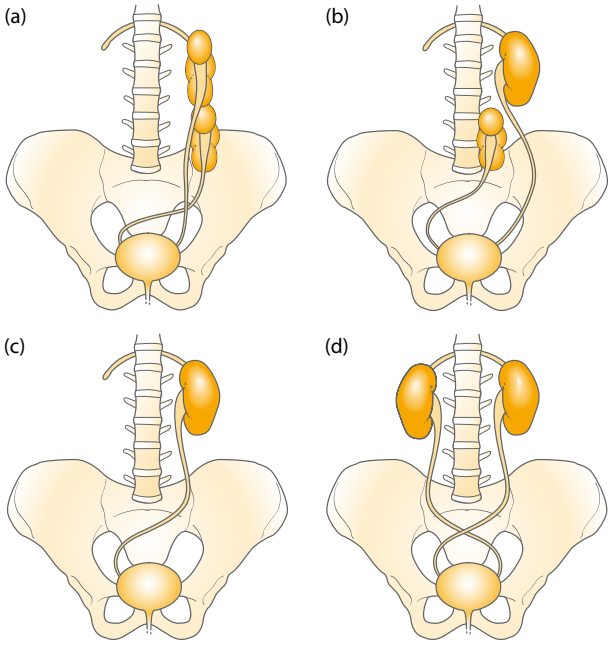

FIGURE 21.21 Four varieties of crossed renal ectopia: (a) with fusion; (b) without fusion; (c) solitary; and (d) bilateral. (Redrawn from McDonald JH, McClellan DS. *Am J Surg* 1957;93:995–1002; as reproduced by Abeshouse BS, Bhisitkul I. *Urol Int* 1959;9:63–91.)

rotation. The second most common type is the sigmoid, or S-shaped, kidney. The crossed kidney is inferior, but both kidneys have completed their rotation so that the two renal pelves face in opposite directions. The fusion of the two kidneys probably occurs later, after axial rotation is completed.

The other four types of fusion are much less common. The lump, or "cake," kidney and the "disk" kidney both involve extensive fusion of the two renal masses. In an L-shaped kidney, the crossed kidney assumes a transverse position. The least common type is the superior ectopic kidney, in which the crossed ectopic kidney lies superior to the normal kidney. The two kidneys may also fuse side to side and ascend together to the renal fossa (Figure 21.23).

Diagnosis

Historically, excretory urography identified most cases of crossed renal ectopia, but currently, US and DMSA radionuclide renal scans have revealed more asymptomatic cases.[44] The vascular supply to these kidneys is quite variable.

Renal arteriography often demonstrates multiple anomalous branches to both kidneys arising from the aorta, or common iliac artery. Rarely will the renal artery cross the midline to supply the crossed kidney.[133]

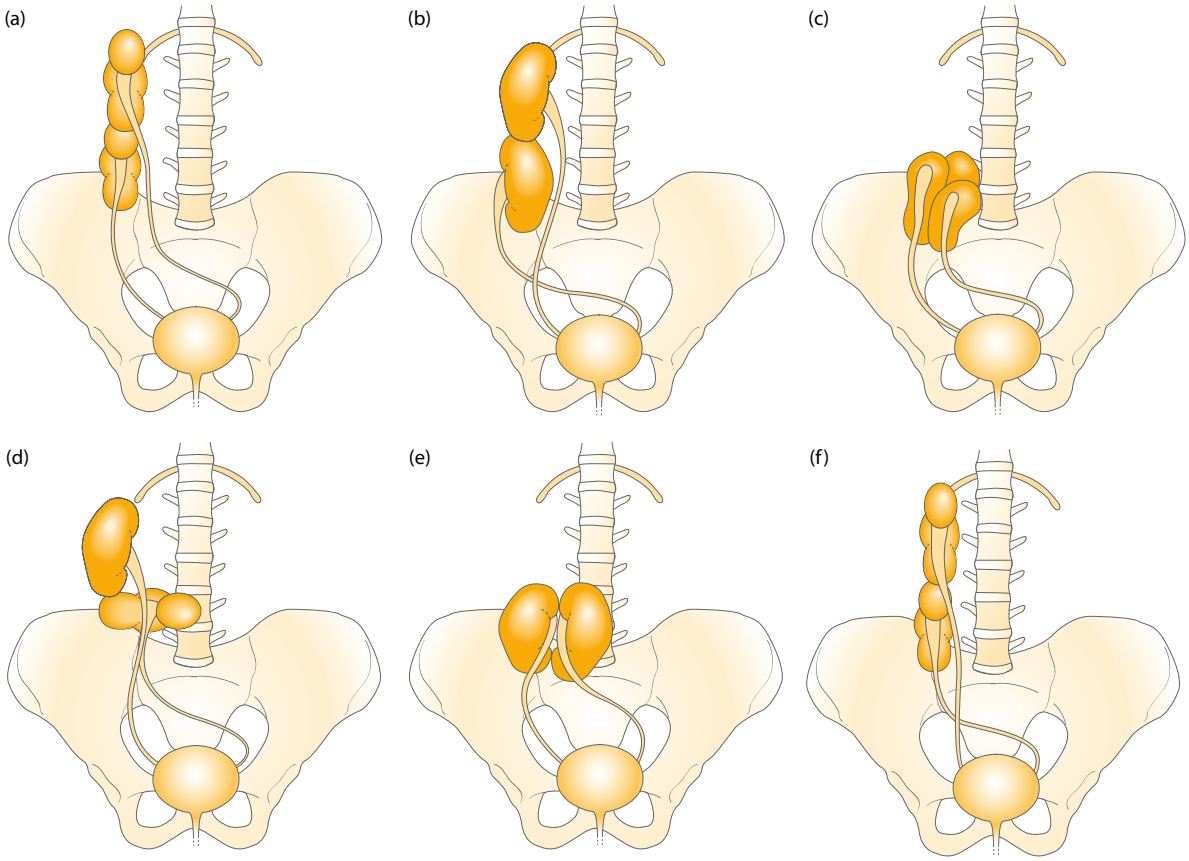

FIGURE 21.22 Six varieties of crossed renal ectopia with fusion: (a) unilateral fused kidney, superior ectopia; (b) sigmoid or S-shaped kidney; (c) 'lump' kidney; (d) L-shaped kidney; (e) 'disk' kidney; and (f) unilateral fused kidney, inferior ectopia. (Redrawn from McDonald JH, McClellan DS. *Am J Surg* 1957;93:995–1002; as reproduced by Abeshouse BS, Bhisitkul I. *Urol Int* 1959;9:63–91.)

FIGURE 21.23 Crossed fused ectopia. Intravenous pyelogram of a child with crossed ectopia, without obstruction.

Associated Anomalies

There is an increased incidence of other malformations, including orthopedic or skeletal anomalies, imperforate anus, and septal cardiac defects.[80] The highest incidence of associated anomalies occurs in children with solitary renal ectopia and involves both the skeletal system and genital organs.[84] This is most likely related more to renal agenesis than to the ectopic anomaly per se (see the "Unilateral Renal Agenesis" section). Fifty and forty percent of solitary crossed renal ectopia have a skeletal or genital abnormality, respectively.[134] The most common genital abnormalities in males are cryptorchidism and the absence of the vas deferens; in the female, it is vaginal atresia or a unilateral uterine abnormality.[131]

The ureter in the crossed ectopic kidney usually enters the bladder, and its orifice is only rarely ectopic.[80] The most commonly associated abnormality is VUR, which is frequently noted in the ectopic kidney.[85] Less common problems include UPJ obstruction, renal dysplasia, and renal tumors.[135]

Prognosis

Most patients with crossed renal ectopia have normal longevity and are discovered incidentally, often by antenatal sonography when two kidneys are not identified.[81] When symptoms do occur, they are often related to infection and obstruction. Abeshouse and Bhisitkul[80] reported that one-third of patients had pyelonephritis and one-quarter had hydronephrosis (Figure 21.24). The caliceal dilatation

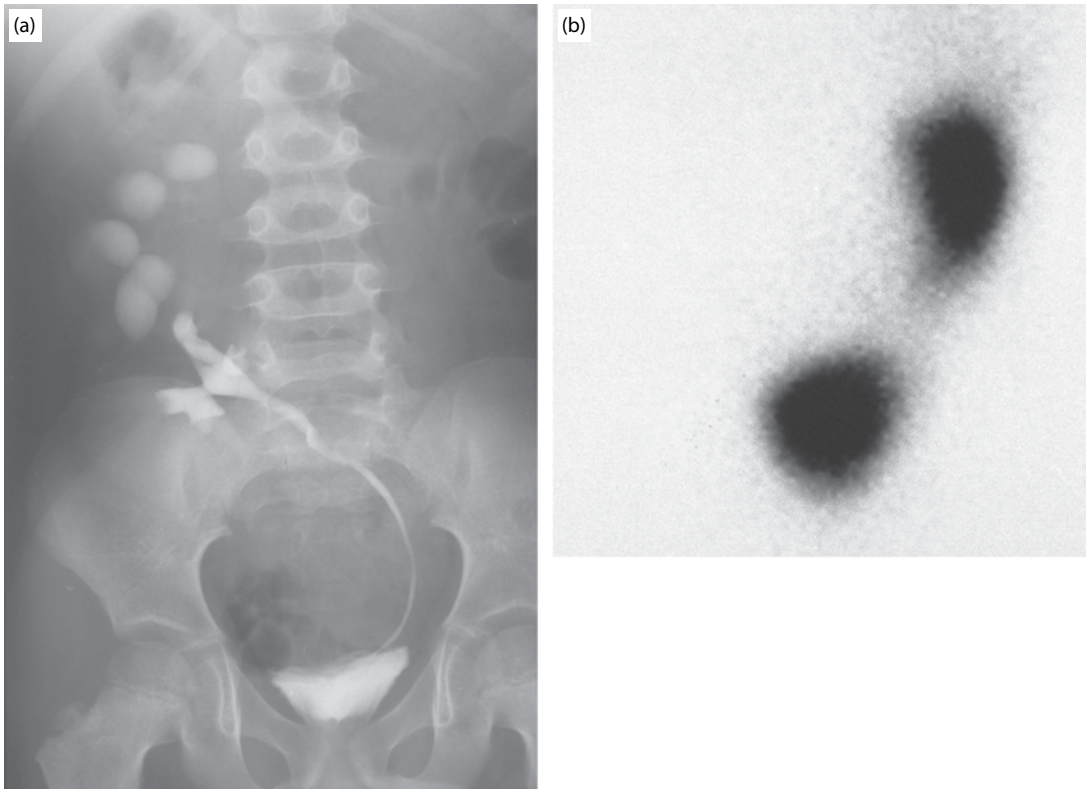

FIGURE 21.24 Crossed fused ectopia. (a) The left kidney crosses the midline. The presence of fusion is difficult to ascertain with confidence on this intravenous pyelogram. Obstruction is noted in the normally positioned right kidney. (b) 99mTc MAG3 radioisotope scan shows increased tracer activity in the right abdomen only.

and distortion may be secondary to the malrotation or the presence of VUR. Urolithiasis has been found in up to one-third of patients.[109]

CHAPTER 22

Fetal and Neonatal Renal Function

Rakesh Rao and Akshaya J. Vachharajani

INTRODUCTION

The intrauterine function of transfer of solutes and removal of waste products is primarily carried out by the placenta. Although immature compared with the adult kidneys, fetal kidneys are uniquely adapted for their primary intrauterine function, i.e., to contribute to the amniotic fluid, and at the same time are capable of regulating fluid, solute, and water balance even at extremes of viable preterm gestation.

MORPHOLOGIC DEVELOPMENT

The excretory system's major role is allowing small molecules to form the blood to be excreted into urine and, at the same time, allowing reabsorption of water and electrolytes. Three evolutionary excretory systems can be identified (Figure 22.1):

1. *Pronephros*: One pair of kidneys consisting of a few primitive nephrons connected to the unbranched nephric duct, e.g., in invertebrates.
2. *Mesonephros*: Pair of kidneys that consist of a linear array of nephrons connected to the unbranched nephric duct, connected to the gonad in males, e.g., amphibians.
3. *Metanephros*: The nephrons are only indirectly connected to the nephric duct, as seen in higher mammals and humans.

In humans, the formation of the metanephric kidneys is preceded by the development and involution of the pronephros (day 22, eight- to nine-somite stage) and mesonephros in a temporal and anteroposterior sequence. All three originate from the intermediate mesoderm.

The pronephros contains rudimentary tubules opening into the pronephric duct that regress by the fifth week. The pronephric duct persists as a mesonephric duct (or Wolffian duct) and evolves into the ureteric bud (UB) (appears around the fourth to fifth week gestation) that is required for the formation of the metanephros. The mesonephros appears caudal to the pronephric tubules between the 3rd and 4th weeks and persists until about the 12th week of gestation. It is also the first definitive functioning kidney in humans characterized by the development of vascularized glomeruli-like structures connected to the proximal and distal tubules that drain into the mesonephric duct. The renal vasculature is primarily derived from the progenitor cells in the metanephric mesenchyme (MM).[1]

In males, the mesonephric duct gives rise to the vas deferens and epididymis, whereas they involute completely in females. The mesonephric ductules give rise to efferent ductules in males and can persist as epoöphoron and paroöphoron in females.

The metanephric kidney develops by reciprocal and sequential inductive interaction between the epithelial UB and the MM and reaches its final lumbar position by the eighth week of gestation.[2,3] The UB induces the formation of epithelial nephrons from the MM cells (mesenchyme-to-epithelial transformation [MET]), whereas the mesenchyme induces the UB to extend and branch (branching morphogenesis).[1,3,4] The UB draws the MM cranially to the final lumbar position of the kidneys by the eighth week of gestation.

Glial-derived neurotrophic factor (GDNF), a member of the transforming growth factor β (TGF-β) family, is the major growth factor secreted by the MM and acts via tyrosine kinase receptor *RET* (REarranged during Transfection proto-oncogene) and its coreceptor GFRα1; it is responsible for the proper positioning and branching of the UB. Mice lacking *Ret*, *Gdnf*, or *Gfrα1* develop renal hypoplasia or agenesis.[5–7] GDNF-RET signaling is positively regulated by several genes and factors, including *Hox11*, *Odd*, and *Pax2/8*. Transcription factors FOXC1 and FOXC2 secreted by the MM are important in regulating GDNF gradient. Sprouty 1 and Bmp4 also play important roles in UB branching. Other growth factors, including fibroblast growth factor (FGF), TGF-β, and Wnt family, are important in the MET process.[1,3,4,8]

The UB epithelium gives rise to the collecting system, including the collecting ducts, calyces, pelvis, ureter, and bladder trigone.[9] The MM differentiates into the glomeruli, proximal tubules, loop of Henle, distal tubular segments, and renal interstitium.[9] Two distinct processes occur concurrently resulting in the final renal architecture (architectonics and nephrogenesis) and are complete by 34–36 weeks of gestation. Renal growth beyond this period is a result of enlargement of the existing nephrons and the interstitial tissues. The renal vascular development parallels the patterns of growth of the UB and nephron formation and is completed by 15 weeks of gestation.

The renal architecture is predominantly determined by the branching pattern of the UB, which in turn determines the topographic distribution of the nephron. The UB first

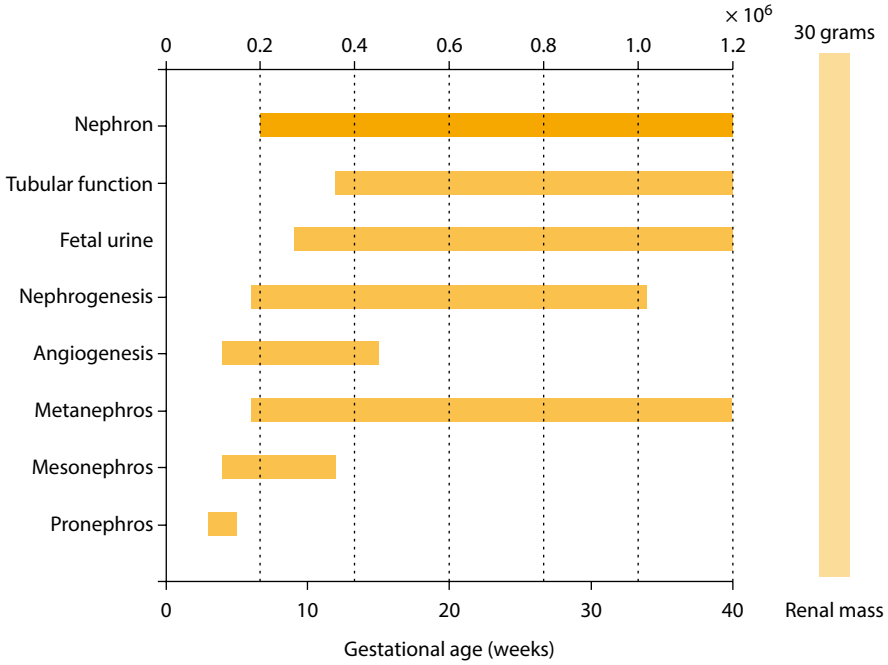

FIGURE 22.1 Schematic fetal renal development: The various aspects of renal development are shown. The UB appears around 5 weeks of age. By approximately 20 weeks of gestation, the fetal kidneys have 1/3 of the nephrons and 1/10 of the renal mass.

branches in a bifid manner, resulting in two daughter branches, although some lateral and trifid branching may occur until terminal bifid branching occurs. Each nephron connects to one ureteric tip, at which point branching ends. A small proportion of nephrons develop following a poorly understood late-phase branching.

Four distinct phases can be identified in the renal structural development based on the branching of the ampulla of the UB.

- *Period 1 (embryonic weeks 5–14)*: Ampullae actively divide and induce nephrons only when not carrying an attached nephron.
- *Period 2 (embryonic weeks 14–15 to 20–22)*: Ampullae rarely divide but induce nephrons when carrying an attached nephron—arcade formation.
- *Period 3 (embryonic weeks 20–22 to 32–36)*: Ampullae do not divide and induce nephrons only when not carrying an attached nephron.
- *Period 4 (embryonic weeks >36 to adulthood)*: Ampullae do not divide and do not induce nephron formation.

Similar to the formation of the renal architecture, nephron formation undergoes four distinct stages following the interactions between the UB and MM (Figure 22.2):

1. Condensation or aggregation: The MM cells aggregate around the UB tip (condensing mesenchyme).
2. Proliferation and development into renal vesicles.
3. Proliferation and development into comma- and S-shaped bodies.
4. Elongation and fusion with the duct.

The S-shaped body is a precursor to glomerulogenesis and tubulogenesis depending on the spatial segmentation of the S shape.[3,8] The proximal tubule and the loop of Henle arise from the lower and middle limbs, and the distal tubule from the upper limb of the S-shaped body, and fuse with the collecting duct. The first nephrons lie near the corticomedullary junction, and the last lie in the outer cortex.[1,3]

PHYSIOLOGIC ADAPTATION AT BIRTH

Body Composition

The predominant component of the human body is water, followed by solids (organs and tissues) and adipose tissue. Body water is distributed into several interconnected distinct compartments. Total body water (TBW) is the sum of all water present, both intracellular water (ICW) and extracellular water (ECW).[10–12] ECW consists of *plasma* (intravascular water), *interstitial fluid* (water surrounding the cells), and *transcellular water* (ECW enclosed by epithelial membrane, such as aqueous humor and cerebrospinal fluid, and water normally present in the respiratory, genitourinary, and gastrointestinal systems). Interstitial fluid volume is estimated as the difference between ECW and plasma (Interstitial fluid volume = ECW – plasma), and ICW as the difference between TBW and ECW (ICW = TBW – ECW).

In the fetus, TBW accounts for the majority of body weight. With advancing gestation, the fraction of TBW as a percentage of body weight of the fetus decreases as the amount of minerals and adipose tissue deposition increases (Figure 22.3). TBW accounts for almost 90% of body weight in the first trimester, ~86% at 24 weeks, 80% by 26 weeks of gestation, and approximately 75%–78% at term. This decrease in TBW is at the expense of a decrease in ECW and an increase in ICW. The decrease in ECW

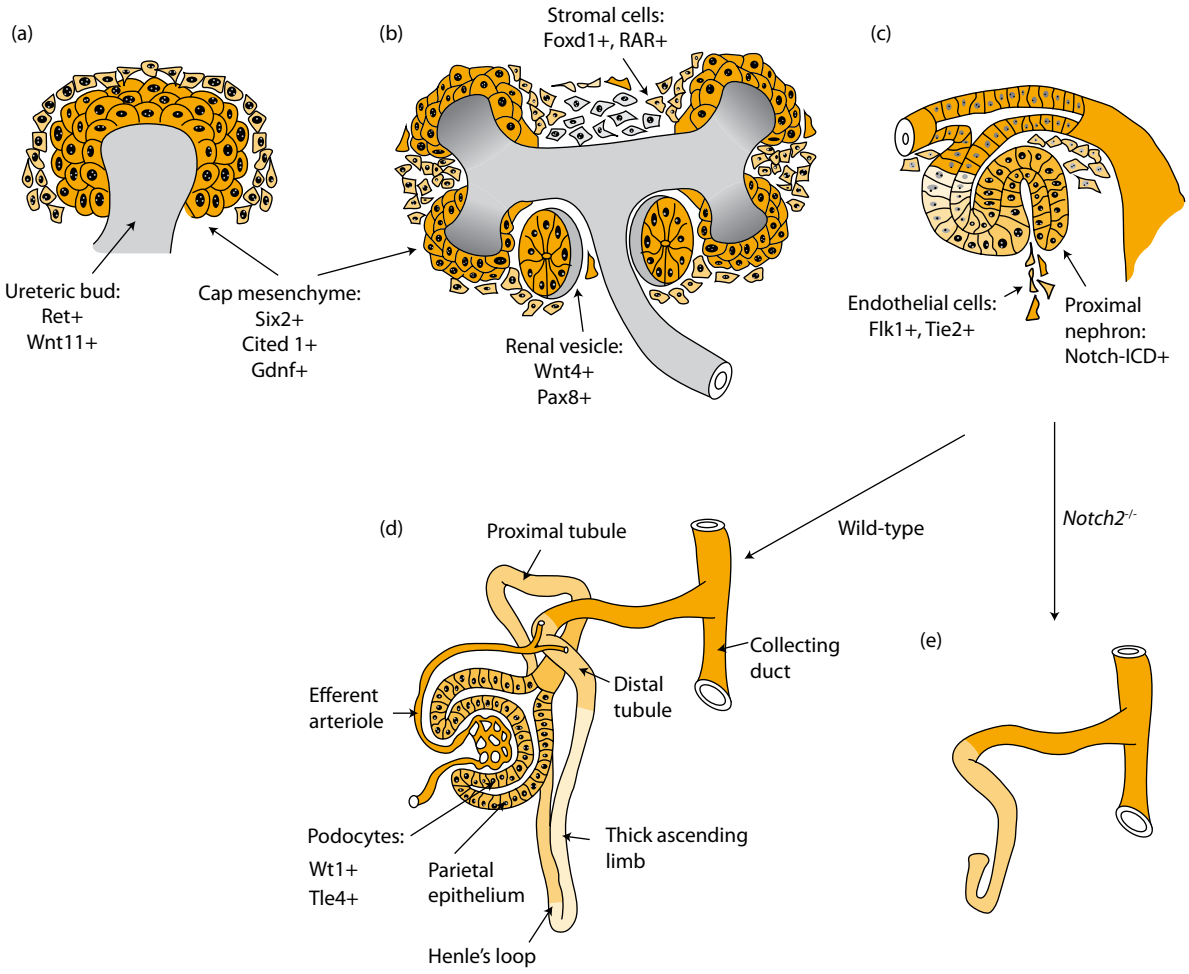

FIGURE 22.2 Nephron development and associated markers. (a) Invasion of UB (gray) and MM (orange). (b) Formation of renal vesicle from the cap mesenchyme. (c) Formation of ureteric stalk that forms the collecting duct and develops the S-shaped body with proximal and distal clefts. (d) Formation of nephron with glomerulus, elongation of proximal tubules, and loop of Henle. (e) Notch signaling determines the proximal-to-distal pattern of the nephron. (Adapted from Dressler GR. *Development* 2009;136(23):3863–74.)

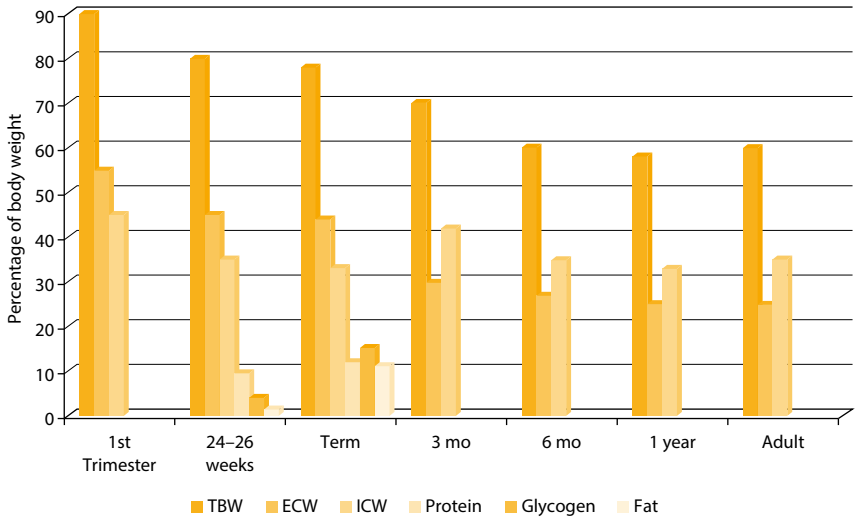

FIGURE 22.3 Contribution of body water compartments shown as a percentage of body weight. The TBW and ECW contributions to body weight decrease with advancing GA. Note the increase in glycogen, fats, and protein with GA.

is due to a decrease in interstitial fluid volume, as plasma volume (as percent of body weight) remains relatively constant across all ages. TBW accounts for 50%–70% of body weight in adults and varies inversely with body fat content. Obese people and women have a higher fat content, and therefore lower TBW.

TBW reaches adult values by 1 year of age (60% of body weight in males and 50% in females). There are similar changes in ECW distribution, with ECW accounting for 60% of TBW at 24 weeks and 44% by term.[13] Therefore, in a healthy term newborn TBW accounts for about 75%–78% of body weight, of which 44% is ECW, 34% is ICW, and 22% is solids. In adults, TBW is ~60% of body weight (ECW = ~33% of TBW) and ECW is ~20% of body weight.

After birth, there is a decrease in TBW that is disproportionately due to loss from the ECW compared with the ICW, particularly in the appropriately grown (appropriate for gestational age [AGA]) preterm infant. This loss from the ECW is due to loss of interstitial fluid without loss of plasma volume. The weight loss secondary to this postnatal diuresis is inversely related to the gestational age (GA) at birth; i.e., the lower the GA, the higher the weight loss. The exact reason for this diuresis remains debatable, but of importance in premature infants, the lack of adequate diuresis and weight loss is associated with worse morbidities, specifically that of bronchopulmonary dysplasia (BPD). In contrast to AGA preterm infants, small for gestational age (SGA) infants have less postnatal weight loss after birth, which has been ascribed to catabolism rather than shrinkage in the ECW compartment.[14] Delayed cord clamping that helps to increase total body iron stores in premature infants may result in an increase in plasma volume.

RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Renal blood flow (RBF) and the glomerular filtration rate (GFR) in the fetus are low compared with those in adults and can be attributed to the smaller kidney size, decreased number of glomeruli, lower systemic pressure, and high renal vascular resistance. Effective renal blood flow (ERBF) measured using p-aminohippuric acid (PAH) may underestimate RBF as the renal extraction of PAH is decreased in the first 3 months of life (due to shunting of blood to the non-PAH-extracting tissues).

The fetal kidneys receive less than 5% of the fetal cardiac output, which increases to ~15% of the total cardiac output after birth and reaches 25% by adulthood. In utero, RBF (measured by color-pulsed Doppler flow) increases exponentially between 20 and 40 weeks of gestation by nearly 10-fold in conjunction with nephrogenesis. RBF increases with GA and is higher in adults than in newborn infants. Interestingly, the increase in RBF after birth correlates with postconceptional age rather than postnatal age.[15] ERBF increases from 20 mL/min/1.73 m^2 at 30 weeks of gestation to 45 mL/min/1.73 m^2 by 35 weeks of gestation, and to 83 mL/min/1.73 m^2 at term. By 3 months of age, ERBF increases to 300 mL/min/1.73 m^2, and to 650 mL/min/1.73 m^2 by 12–24 months of age.[16,17]

The glomerular arterioles are the primary site of renal vascular resistance that determine the renal as well as the intrarenal distribution of blood flow. Blood flows into the glomerulus via the afferent arteriole that arises from the interlobular artery and exits via the efferent arteriole. With advancing GA, renal blood increases to all areas of the kidney: the cortex (containing the glomeruli), medulla (tubules and the vasa recta), and papillary area. The neonatal kidney, compared with the adult kidney, receives more blood in the inner cortical and the medullary area than the outer cortical layer. RBF is also dependent on arterial blood pressure and the blood volume.

After birth, renal vascular resistance decreases and RBF increases. The increase in RBF is dependent on changes in cardiac output, perfusion pressure, and renal vascular resistance, as well as the presence of vasoactive substances, rather than on anatomic factors alone, as nephrogenesis is complete before term birth in humans (but continues in dogs and rodents). Vasoactive substances act by altering the participation of the vascular beds (interlobular, afferent, and efferent arterioles) and affecting the intrinsic myogenic responses of the resistance vessels that are unique to the immature kidney.[17] Several vasoconstrictive substances (endothelins, renin angiotensin system, and arginine vasopressin) and vasodilators (adenosine, nitric oxide [NO], bradykinin, and natriuretic peptides) act together to modulate RBF, as discussed further briefly below (Table 22.1).

Angiotensin II is one of the most potent vasoconstrictors in the immature kidney. Circulating levels of renin and angiotensin II are higher in the more immature kidney and decrease after birth. Angiotensin II acts via the angiotensin receptors AT 1–4, of which AT-1 and AT-2 may also be involved in renal angiogenesis and nephrogenesis. AT-1 receptors cause vasoconstriction and are expressed in the kidney on the glomerulus, arterioles, and medulla, and its gene expression increases after birth; the expression of AT-2 is seen earlier in gestation, and its expression decreases after birth.[19,20] AT-1 receptor antagonists produce renal defects similar to those seen with intrauterine exposure to angiotensinogen-converting enzyme inhibitors, and disruption of AT-1 and AT-2 receptors leads to malformations of the kidney and urinary track. In lambs, inhibition of AT-1 receptor, but not AT-2 receptor, causes a decrease in renal vascular resistance and an increase in RBF.[17]

NO, produced by the vascular endothelium, is a potent vasodilator. Nitric oxide synthase (NOS) is present as distinct isoforms: in the endothelium (eNOS) and as inducible (iNOS) and neuronal (nNOS) nitric oxide. NO production is most abundant in the immature kidneys compared with adults, with nNOS being expressed abundantly in the cortex and the medulla. Blockage of NO production causes renal vasoconstriction that is mediated via angiotensin II.[21,22]

RBF remains constant despite alterations in renal perfusion pressure (autoregulation), although over narrower ranges with decreasing gestation. With increasing maturity, autoregulation of the RBF is also determined by the relationship between the GFR and tubular flow (tubuloglomerular feedback). As the GFR increases, the tubular flow and responses also increase, so that the relative sensitivity of the feedback mechanisms remains relatively unchanged.[17]

TABLE 22.1 Vasoactive substances in the kidney

	Action	Site	Effects
Adenosine Regulates intrarenal blood flow	Vasodilator A1 receptor: Inhibits renin release and afferent vasoconstriction A2: Stimulates renin release and afferent/efferent dilation	Increases medullary against cortical blood flow via the A2 receptor Increases RBF and decreases efferent vascular resistance	Tubuloglomerular feedback Protect medulla from hypoxic injury
Bradykinin Intrarenal vasodilator	Opposes action of angiotensin II in the immature kidney?		Role in maturational increase in RBF?
Endothelins 3 peptides, ET 1–3	ET-1: Afferent and efferent arteriolar constriction via ETA receptors ET-2 ET-3	ETA receptor in tunica intima: Vasodilation ETB receptor in tunica media: Vasoconstriction	ETB1 receptor: Vasodilator ETB2 receptor: Vasoconstrictor
Arginine vasopressin	V1a receptor: Arteriolar vasoconstriction	Glomerular and arteriolar	
Atrial natriuretic peptide	Atria and ventricles: Respond to volume	Proximal and distal tubules	Renal vasodilation, decrease blood pressure Increase RBF and GFR Inhibit Na and water reabsorption and urine concentration
Angiotensin (1–7)[19]	Site specific	Proximal tubules, renal vascular cells, and glomerular epithelium	Vasodilation of preconstricted afferent arterioles (via NO) Blocks transcellular sodium transport Counteracts angiotensin II–mediated hypertrophic effects

Fetal GFR increases in parallel to the increase in RBF, from <1 mL/min at 20 weeks' gestation to 5 mL/min at term.[15] This increase is attributable to the increase in surface area of the glomerular basement membrane determined by the number and degree of maturation of glomeruli as they limit the amount of fluid that can be filtered.[23] Further, GFR is also dependent on the RBF, blood volume, arterial blood pressure, and glomerular permeability. GFR at birth is proportional to the GA (Figure 22.4); however, regardless of GA, the GFR doubles within 2 weeks of birth, attributable mostly to the increase in the net filtration pressure and ultrafiltration coefficient.[24] In very low-birth-weight infants, catch-up in GFR may take several months.[15] Genetic and environmental factors can affect fetal GFR; for example, antenatal exposure to angiotensinogen inhibitors (captopril and enalapril) and prostaglandin (PGE) inhibitors (indomethacin) reduces GFR.[25]

Tubular Handling of Sodium and Potassium

Sodium and potassium accretion are important for fetal and neonatal growth. However, the regulation of sodium and potassium and their transport vary.

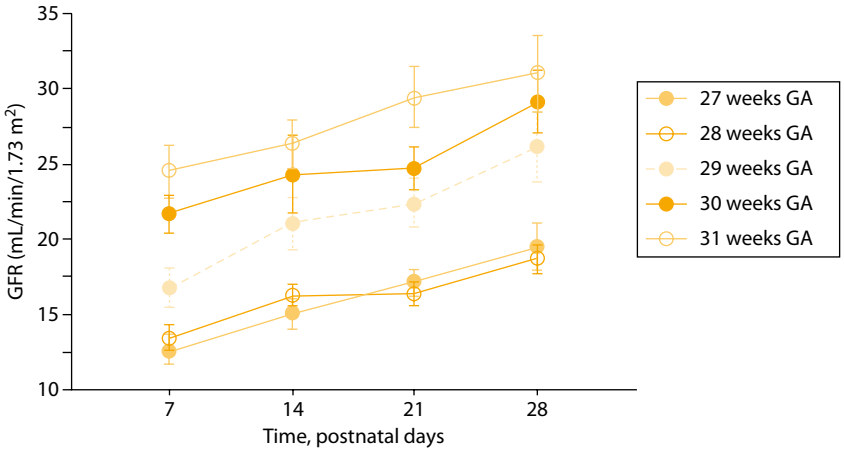

FIGURE 22.4 GFR in preterm infants is inversely proportional to the GA. (From Vieux R et al. *Pediatrics* 2010;12(5):e1186–92. With permission.)

Sodium handling by the kidney depends on the stage of fetal and neonatal maturity. The fractional excretion of sodium (FE_{NA}) measures the tubular sodium transport that is "normalized" for the GFR. FE_{NA} is calculated by

$$\frac{\left(\begin{array}{l}\text{Urinary concentration of sodium } (U_{NA}, \text{mEq/L}) \\ \quad \times \text{Urine volume/unit time}\end{array}\right)}{\left(\begin{array}{l}\text{Creatinine clearance} \\ \quad \times \text{Plasma sodium concentration } (P_{NA}, \text{mEq/L})\end{array}\right)}$$

or

$$FE_{NA} = (U_{NA} \times P_{cr}) / (U_{cr} \times P_{NA}) \times 100\%$$

FE_{NA} varies inversely with GA and with postconceptional age. Fetal FE_{NA} is very high, with an average of 12.8%. However, before 30 weeks' gestation, FE_{NA} is 5%, but it approaches 1% by term gestation, signifying improving renal maturity for sodium conservation. In fact, this high FE_{NA} puts the fetus of <30 weeks' gestation in a state of negative sodium balance, and it only approaches a positive balance by 36 weeks' GA. When infants are born preterm, the sodium balance is dependent on the severity of prematurity and the degree of sickness. For example, Vanpee et al. noted that the FE_{NA} declined rapidly after birth for infants born at 25–30 weeks' GA and 31–34 weeks' GA and approached term newborn levels by 4–6 weeks after birth.[26] In healthy preterm infants of >33 weeks' gestation, a positive sodium balance is seen by days 2–4 of age, in contrast to sick preterm infants, where higher FE_{NA} and negative sodium balance can persist beyond a week of age.[27] The FE_{NA} in healthy term newborn infants is <1% by 24–48 hours of age.

A negative sodium balance impacts *postnatal* growth, particularly in very low-birth-weight infants. However, while supplementation can prevent late hyponatremia, excessive sodium administration can result in water retention and an increase in ECW. As mentioned previously, lack of adequate diuresis in this population has been associated with an increased risk of BPD.[28]

In preterm infants, both proximal and distal tubular reabsorption of sodium is inversely related to GA. Both in preterm and term infants, the ability to achieve diuresis in response to a renal sodium load is limited compared with in older children due to the functional immaturity of the distal tubule, the site that is primarily responsible for the developmental and postnatal maturation for renal conservation of sodium.[29] In preterm infants of <34 weeks' GA, distal sodium reabsorption is higher, but the fractional distal sodium reabsorption is decreased compared with in term infants during maximal water diuresis.[30]

Since sodium is freely filtered at the glomerulus, several mechanisms at various parts of the nephron act to conserve sodium. In the proximal convoluted tubule (PCT), the fractional reabsorption of sodium remains relatively constant at ~60% by both active and passive mechanisms. The latter is due to the presence of a relatively permeable tubular epithelium and lower tubular hydrostatic and oncotic pressures that allow for passive reabsorption of sodium and other solutes.

Several transport proteins are responsible for the active transport of sodium.[31–33] In the PCT, the expression of the basolateral Na^+ K^+ ATPase pump produces the electrochemical gradient for Na^+ reabsorption. The activity of the Na^+ K^+ ATPase pump and the capacity for active transport increase nearly threefold with advancing gestation and are positively upregulated by aldosterone and glucocorticoid exposure. Further, the distribution of the Na^+ K^+ ATPase pump is also developmentally regulated with differential expression of the β_1 (basolateral, upregulated) and β_2 (apical, downregulated) subunits.

Symporters (family of proteins that transfer solutes from the lumen to the tubular cells) also play an important role in the reabsorption of solutes, such as bicarbonate and phosphate coupled with sodium reabsorption. The sodium hydrogen exchangers (NHEs), a family of membrane proteins (NHE 1–4), are the major transporters of Na^+ in the PCT. They are expressed in the kidneys and gastrointestinal tract, including the stomach, and regulate intracellular pH (NHE-1), sodium (NHE-2 and NHE-3), and bicarbonate (NHE-3) reabsorption. NHE 1, 2, and 4 are amiloride sensitive, whereas NHE-3 is not. Homozygous mutant NHE-3 knockout mice have diarrhea and mild acidosis but are not significantly hyponatremic due to upregulation of aldosterone and colonic epithelial Na^+ and H^+ K^+ ATPase.[34]

Other transporter proteins that contribute to the reabsorption of Na^+ in the PCT include the sodium bicarbonate transporter (NBC) family of proteins (NBC 1–3), which transport Na^+ and HCO_3^- bicarbonate, and the sodium-phosphate Type IIa (Na-P_i) cotransporter, which is rate limiting for cotransport of Na^+ and phosphate. The Na-P_i cotransporter is expressed more robustly in newborn than mature animals and is upregulated in NHE-3 knockout mice.

The thick ascending loop of Henle (TALH) only has 20% absorptive capacity for Na^+ compared with adults due to the lower Na^+ K^+ ATPase activity; thus, more isotonic fluid is delivered to the distal tubule, and with limited absorptive capacity, the urinary concentrating ability in the premature infant is limited.

The epithelial sodium channel (EnaC) expressed on 70% of the distal convoluted tubules and the cortical collecting duct are the principal sites for electrogenic Na^+ transport in the distal nephron. Four functional subunits of EnaC channels (α, β, γ, and δ subunits) have been identified that are present in the lungs and kidneys. The EnaC channels are the ratet-limiting step for Na^+ reabsorption and primarily mediated via aldosterone by binding to its (mineralocorticoid) receptor.[35–37] In experimental aldosterone-sensitive cell lines (A6), aldosterone regulates sodium reabsorption via activation of EnaC through the expression of the small G-protein K-Ras2A in the short term and by regulating the trafficking and degradation of EnaC in the long term. EnaC knockout model mice develop salt wasting and metabolic acidosis and have difficulty clearing lung fluid.[32]

Other cation-Cl^- cotransporters (CCCs) include the chloride-coupled transporters that cotransport Cl^- with Na^+ or K^+, such as the furosemide-sensitive Na-K-Cl cotransporters (NKCC 1 and 2), Na^+-Cl^- cotransporter (NCC), and K^+-Cl^- (KCC) cotransporters and the CCC

interacting protein (CIP).[32] The Na-K-Cl cotransporter expressed in the TALH is responsible for Na^+ and Cl^- transport, and the KCC are inhibited by loop diuretics (see the "Potassium" section below). Lastly, the thiazide-sensitive NCC is the primary determinant of sodium and chloride reabsorption in the distal nephron.

The expression and distribution of renin in the kidneys are spatially and temporally regulated in relation to vasculogenesis. Renin-expressing cells are initially present all along the interlobar and arcuate arteries in the fetus but are limited to the juxtaglomerular portion of the afferent arteriole in adults.[38] Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II antagonist exposure in utero causes a decline in the fetal GFR (reversed by angiotensin II) with an increase in RBF; the fractional reabsorption of Na^+ in the proximal tubule is, however, not affected.[39] Interestingly, the activity of angiotensin II appears to be independent of aldosterone secretion.

Plasma renin activity (PRA) and plasma aldosterone (PA) concentrations are highest in the newborn period. In preterm infants, the lack of exogenous sodium supplementation results in a rapid rise in PRA and PA activity, followed by a more gradual decline. PRA is also inversely correlated with urinary sodium excretion in term infants.[40] Urinary aldosterone excretion (UAE) is similar in preterm and term infants and is higher than in adults.[41] In term but not preterm infants, the urinary Na/K ratio can be used to assess the effect of aldosterone on tubular function, and it has a linear relationship with UAE. The high UAE also corresponds to the period of hyponatremia seen in the preterm infants in the first 2 weeks of life. Further, the renal response to aldosterone is blunted in preterm infants compared with term infants at the postreceptor level.

PGE is a regional vasodilator and counteracts the vasoconstrictive effects of the renin–angiotensin system; use of PGE antagonists like indomethacin can result in decreased renal and glomerular blood flow and GFR. Sodium supplementation decreases PGE activity.

Lastly, sodium and water reabsorption are also mediated via catecholamines, atrial natriuretic peptide, and digoxin-like substances.[32]

Potassium

Potassium is the most abundant intracellular cation, with an intracellular concentration of 100–140 mEq/L maintained by the Na^+ K^+ ATPase pump. The Na^+ K^+ ATPase pump by active cytosolic hydrolysis of ATP extrudes three molecules of Na^+ for the uptake of every two molecules of K^+. Muscles are the primary intracellular reservoir, with 98% of total body potassium; the remaining 2% is distributed in the extracellular fluid.

Potassium is conserved by the fetus for growth, particularly after 30 weeks' gestation. Postnatal growth is associated with an increase in total body potassium from 8 to 14 mEq/cm body height from birth to adulthood, respectively. Fetal potassium concentrations are maintained above 5 mEq/L; newborn infants therefore have higher plasma potassium concentrations at birth, with higher levels in the more immature (up to 6.5 mEq/L). The urinary Na/K ratio in the newborn may exceed 1 (normal 0.5–0.6) up to 4 months of age in term infants and may be >2 in infants of <34 weeks' gestation due to relative nonresponse to mineralocorticoids in preterm infants.[42]

Extremely preterm infants, <28 weeks, develop nonoliguric hyperkalemia (>6.5 mEq/L) within 48 hours of birth, even without any potassium intake. Low Na^+ K^+ ATPase pump activity, limited renal potassium secretory capacity, and developmental expression of potassium transporters may all play a role.[42] The nonoliguric hyperkalemia is, however, not seen in the more mature or term infants. Antenatal steroids for fetal lung maturation also cause maturation of the Na^+ K^+ ATPase pump and may prevent this phenomenon.

Adults excrete 90%–95% of daily potassium intake via urine (90%) and stool (5%–10%), with nearly 50% of an oral load excreted within 4–6 hours of ingestion. Renal secretion, rather than reabsorption, is the dominant mechanism of potassium homeostasis in a fully mature kidney.

In contrast, renal potassium clearance and excretion per unit body weight or kidney weight is lower in newborn infants even when corrected for the lower GFR. However, in response to potassium challenge, newborn infants are capable of secreting potassium, albeit at lower rates than adults. The fractional excretion of potassium is reduced by 50% between 26 and 30 weeks' GA despite a near threefold increase in the filtered load of potassium during this period, suggesting that the immature kidneys are also capable of reabsorbing potassium.[44]

Potassium is freely filtered into the glomerulus, and nearly 65% is passively reabsorbed, along with sodium and water in the PCT. The TALH, which absorbs potassium in adults, is not fully mature in newborn infants. The cortical collecting ducts are the final site of K^+ excretion but are limited in their capacity to excrete K^+ in newborn infants compared with adults.[45–47] Data from rodent experiments suggest that nearly 35% of the filtered potassium load reaches the distal tubule in 2-week-old rats, compared with 10% in human adults. The absorption of potassium in the TALH is regulated by the Na^+, K^+, and $2Cl^-$ cotransporter (blocked by loop diuretics, such as furosemide and bumetanide) along an electrochemical gradient created by the basolateral Na^+ K^+ ATPase. The activity of the Na^+ K^+ $2Cl^-$ transporter also requires the presence of a luminal secretory potassium channel encoded by the rat outer medullary K^+ channel (*ROMK*) gene. Loss-of-function mutation of the ROMK gene is associated with neonatal Bartter's syndrome (polyhydroamnios, salt wasting and dehydration, hypercalciuria, hyperreninism, hyperaldosteronism, and normal blood pressure presenting in the first week of life).

Potassium secretion in the collecting duct and the distal tubule contributes to the urinary potassium excretion and can approach 20% of the filtered load in adults. The *principal cells* are primarily responsible for the absorption of Na^+ and K^+, while the *intercalated cells* absorb K^+ in response to potassium restriction or acidosis.[45] In the principal cells, Na^+ K^+ ATPase transports K into the cell at the expense of Na^+ to build a concentration gradient, thus allowing K^+ to passively diffuse out into the lumen via two secretory channels: (1) the small-conductance (SK) channel encoded by the *ROMK* gene that mediates baseline potassium secretion, and (2) the high-conductance calcium- and stretch-activated maxi-K channel that regulates

flow-stimulated potassium secretion.[45] Potassium reabsorption in the distal kidney is regulated by the H^+ K^+ ATPase localized in the intercalated cells.

The postnatal increase in potassium secretory capacity is due to developmental increase in the expression of both the SK and maxi-K channels.[47,48] In newborns, potassium secretion in the distal cortical collecting duct cannot be stimulated by increasing the urinary flow rate. Thus, volume expansion or increases in tubular flow rate by diuretics do not increase K^+ secretion in the immature kidney.[45]

Calcium and Phosphorous

In addition to regulating Na^+ and K^+, the kidney also plays an important role in regulating calcium and phosphorous homeostasis.

Ca^{++} is the most abundant mineral in the human body, accounting for almost 2% of total body weight. Calcium deposition within the bones accounts for 98% of total body calcium and is predominantly deposited in the third trimester of pregnancy, along with phosphorous. The kidneys regulate Ca^{++} absorption and excretion in parallel with Na^+ under various conditions, such as acidosis or alkalosis, diuretics use, and alterations in volume status. Less than 2% of the filtered calcium is excreted in the urine, with the majority absorbed by passive transport via the intercellular spaces in the PCT (70%) and the TALH (20%) by voltage-driven paracellular flux; the remaining is reabsorbed by active transcellular transport in the distal convoluted and connecting tubules (10%–15%).[49] The latter is the primary regulator of body Ca^{++} balance and is independent of Na^+ balance.

Active transcellular Ca^{++} transport is a complex multistep process requiring entry via the apical epithelial calcium channels, cytosolic buffering by calcium binding proteins (calbindin-D_{28K}), facilitated diffusion to the basolateral side, and finally, extrusion into the vascular interstitium by sodium calcium exchanger (NCX1) and plasma membrane calcium adenosine triphosphatase (PMCA1b).[49] The first step is the rate-limiting factor regulating calcium reabsorption in the distal tubules.

The epithelial Ca^{++} channel (TRPV5), a member of the transient receptor potential (TRP) channel proteins, is a highly Ca^{++}-selective channel responsible for Ca^{++} influx in epithelial cells and expressed on the apical membrane in the distal convoluted tubule (DCT) and connecting tubule. TRPV5 is responsible for active reabsorption of Ca^{++}. TRPV5 is ubiquitously expressed in the kidneys, intestine, pancreas, brain, prostrate, and testes, and homozygous knockout mice exhibit hypercalciuria, intestinal hyperabsorption of Ca^{++}, and reduced bone thickness. The expression of the TRPV5 gene in turn is regulated by vitamin D3, parathyroid hormone (PTH), and the antiaging hormone Klotho.[50] The calcium-sensing receptor (CaSR), originally described in the parathyroid gland and also expressed in the kidneys, is the major receptor through which extracellular effects of Ca^{++} are mediated. In the developing human kidney, CaSR is expressed on the TALH and distal tubules and inhibits the paracellular absorption of calcium in the TALH.[51]

Phosphorous is present mostly in the bones (80%), two-thirds of which is present as organic phosphorous (esters and phospholipids) and one-third as inorganic phosphate (in plasma bound to calcium, magnesium, or protein). Plasma concentrations of phosphate are highest in neonates compared with children and adults. The nonprotein-bound fraction of phosphate (~90%) is freely filtered across the glomerulus, and 75%–85% of the filtered phosphate load is reabsorbed in the PCT. The remaining is excreted as titrable acid in urine. A small fraction is reabsorbed in the distal collecting or connecting tubule in adults.

The tubular reabsorption of phosphate is a saturable process and is dependent on the GFR. However, despite the low GFR in newborn infants, phosphate reabsorption is increased and urinary excretion limited in periods of growth in the preterm infants despite high plasma phosphate levels. Phosphate reabsorption is also higher in the deeper juxtamedullary nephrons than in the more superficial nephrons, and likely contributes to the higher phosphate reabsorption in utero. In states of phosphate conservation, reabsorption of phosphate also occurs in the DCT, the proximal straight tubule (pars recta), and the collecting tubule, but not in the loop of Henle, due to low permeability. As mentioned previously, phosphate transport is coupled with sodium via the Na^+-dependent Pi family of cotransporters (Na-Pi Types I–III). Of these, the Na-Pi Type II family (IIa, IIb, and IIc) is most involved in regulating Na^+ and phosphorous transport, particularly the Type IIa isoform expressed in the proximal tubule.[52,53] The increase in tubular reabsorption of phosphorous may be directly related to the increase in the expression of this isoform with increasing maturation. Several other factors, including thyroid, parathyroid, and growth hormones; dietary phosphate intake; and phophatonins (autocrine–paracrine factors that affect tubular phosphate uptake), such as FGF23, also influence renal phosphate regulation.

Although transfer across the placenta is the major source of protein deposition in the fetus, the kidneys also play an important role in regulating amino acid and organic acid homeostasis. The PCT is the primary site for reabsorption of amino acids following glomerular filtration. With the exception of taurine and glycine, nearly 80% of the filtered amino acids are reabsorbed by active processes across the tubular luminal brush border with little passive diffusion.[54,55] Following intracellular active transport across the apical membrane with Na^+- or H^+-coupled symporters (the Na^+ neutral amino acid transporter B^0 AT-1 transports 80% of free plasma neutral amino acids), amino acids mostly passively efflux across the basolateral membrane. The basolateral Na^+ K^+ ATPase pump actively pumps Na^+ out of the tubular cells into the intercellular space, creating a concentration gradient at the brush border for Na^+ to enter the cell from the tubular lumen and cotransporting amino acids with it. Since most amino acids are transferred by non–amino acid–specific group cotransporters, disease states such as cystinuria result in additional loss of arginine, ornithine, and lysine. Preterm infants are often noted to have *developmental aminoaciduria*, with failure to reabsorb amino acids in the PCT likely from differential maturation of the brush border transporters that allow for amino acids and Na^+ influx and mechanisms that allow for amino acid efflux from the cell into the perivascular blood vessels.[56] Several groups of

amino acid transporters have been identified at the brush border, of which the Na^+- and Cl^--dependent transporters (GAT family) are the most important. Others include the cationic amino acid transporters (CAT family), glutamate transporters, and cationic neutral amino acid transporters (rBAT family). Immaturity of the brush border absorptive mechanisms may result in amino acid deficiency, such as taurine, which becomes conditionally essential in preterm infants.

Organic acids, such as hippuric acid, uric acid, and antibiotics (coupled with organic acid transporters), are actively secreted by the PCT. Several organic acid–specific (OAT), urate-specific (URAT), and organic cation–specific (OCT) transporters allow for active transport of organic acids against a concentration gradient.[57–59] An increase in RBF and GFR, in addition to the increase in the expression of these transporters, results in an increase in tubular transport capacity and an increase in urine organic acid excretion with advancing GA. Elimination of organic drugs by renal tubular secretion, such as penicillin, is therefore maturation dependent.

URINE CONCENTRATION AND DILUTION

Although the fetal kidneys are capable of concentrating and diluting urine, albeit not similar to adults, the primary purpose of fetal urine production is to provide adequate amniotic fluid volume: the excretory functions are carried out by the placenta. Fetal urine is hypotonic compared with fetal plasma. After birth, the kidneys conserve water and excrete a solute load under healthy and diseased states.

Anatomical, functional, and developmental differences contribute to the limited fetal and neonatal renal function. Shorter loops of Henle, limited salt reabsorption in the ascending loop of Henle, greater medullary RBF per nephron compared with the cortex despite a higher cortical-to-medullary blood flow, and limited fetal response to antidiuretic hormone (ADH) (discussed below) are some of the factors that limit the efficacy of the medullary osmotic gradient necessary to concentrate urine fully in the fetus and neonates compared with an adult. Detailed reviews of the mechanisms of urine concentration and dilution are available[60,61] and discussed briefly below.

The movement of water from the tubular lumen and along the interstitial gradient depends on ADH and the tubular vasculature. The development and maintenance of the interstitial osmotic concentration gradient is determined by urea. Vasopressin increases urea permeability in the terminal inner medullary collecting ducts by increasing expression of the urea transporters (UT-A1 and UT-A3).[61] Fluid absorption in the PCT is isotonic; concentration occurs primarily in the loop of Henle and the collecting tubules. In the latter, water is absorbed along an osmolar gradient under the influence of ADH and by active NaCl absorption in the thick TALH.

The TALH in the outer medulla is capable of absorbing NaCl in the relative absence of water, resulting in the dilution of the tubular fluid; TALH is also impermeable to water, thereby allowing the urine to be more dilute and more isotonic as it enters the distal convoluted and collecting tubules. Vasopressin stimulates NaCl reabsorption by the medullary TALH, while it induces water reabsorption from the outer medullary collecting ducts. These actions result in an osmotic gradient and reabsorption of water from the collecting tubules in the outer medulla.

Fetal ADH, expressed by 12 weeks' gestation, is an important regulator of fetal urine production, as the placenta is impermeable to maternal ADH. The urinary concentration increases with advancing gestation due to an increase in reabsorption of free water (under the influence of ADH) relative to the solute (urea). Although the fetal collecting duct expresses ADH receptors, fetal cAMP production in response to ADH is lower than that in adults due to the lower sensitivity to ADH or to a decreased number of ADH receptors. More recently, elevated phosphodiesterase levels have been suggested as the reason for the blunted response to ADH.[23] With advancing gestation, fetal ADH concentrations respond to fetal blood volume, hypoxia, and both osmotic and nonosmotic factors. ADH causes transplacental water retention by inhibiting flow from the fetus to the mother, and regulates fetal blood pressure by redistribution of blood flow to the brain, heart, and umbilical–placental circulations under conditions of fetal stress. Preterm infants with a larger extracellular free water content and relative hyponatremia have a blunted response to ADH in the first few weeks after birth.

Aquaporins (AQPs) (seven have been described in the kidneys so far)—transmembrane proteins expressed in the kidneys and other tissues—regulate water transport.[62] Their expression in the kidneys is developmentally regulated, and they have specific cellular localization. They may or may not be under hormonal control.

AQP-1 expressed in the proximal tubules in the S1, S2, and S3 segments is a major transmembrane pathway that imparts high osmotic water permeability but is not under hormonal control (i.e., ADH). Mice deficient in AQP-1 are polyuric and cannot tolerate water deprivation. AQP-1 expression is decreased at birth compared with in adults. In contrast, AQP-2, expressed on the principal cells in the outer and inner medullary collecting ducts by 20 weeks' gestation, is regulated by ADH, mediates short-term responses to ADH, and plays a role in long-term adaptation to stimuli. For example, AQP-2 downregulation is seen with prolonged lithium use, ureteric obstruction, and chronic hypokalemia and hypercalcemia. In preterm infants, postnatal diuresis is associated with increased AQP-2 excretion in the urine.[63,64] The increasing fetal sensitivity to ADH with advancing GA is due to increased expression of AQP-2. AQP-3 is also present on the principal cells in the collecting ducts and is the major site for osmotically driven water movement. Prolonged water deprivation results in upregulation of AQP-3 expression. AQP-6 is expressed in intracellular vesicles in the intercalated cells of the collecting duct, and AQP-11 is expressed in the endoplasmic reticulum in the proximal tubules. Knockout mice deficient in AQP-11 develop polycystic kidney disease.[62]

The renal medulla is the primary site for urine concentration and dilution. The concentration of urine requires two distinct steps: extraction of water via the water channels (AQPs) and solute (chloride or urea) movement from the ascending loop of Henle (via chloride channels) to the

medullary interstitium to provide a concentration gradient. The countercurrent multiplier system (and the vasa rectae) allows the medullary interstitium to be progressively hypertonic at the same time, allowing osmotic equilibration between the medullary collecting duct fluid and the medullary interstitium. The thin ascending limb of the nephron is permeable to Cl^- and expresses the chloride channel ClC-K1, which allows efflux of NaCl and concurrent water into the interstitium, thus increasing the osmolality of the collecting duct fluid. The absence of this channel results in diabetes insipidus in rats.[65] The expression of the ClC-K1 channel is developmentally regulated and increases with gestation; maturation of this channel allows the establishment and maintenance of the medullary interstitial gradient.

Urea, the final metabolite of protein breakdown, accounts for nearly 50% of the solute load in a maximally concentrated urine. Neonates have lower urea content in the urine (likely from increased utilization for growth) than adults, although the nonurea solute contents are similar. However, when given a protein load, newborn infants can increase their maximal urine osmolality independent of fluid intake or urine output.

Although vasopressin levels are elevated at birth in both preterm and term infants, developmental differences (see above) in ADH concentrations and responses can explain some of the limited concentration capacity of the newborn kidney. In addition, AQPs, PGEs, and an intact renin–angiotensinogen axis play important roles in urine concentration.

Multiple factors in the newborn period contribute to the relative inability of newborn infants to concentrate urine; both preterm and term infants are able to concentrate urine more than 600 mOsm/kg soon after birth.[66,67] Term infants reach adult levels by 2 years of age.[23] The renal concentration capacity for urine is directly dependent on the length of the loops of Henle as they descend into the medulla. In rabbits, a postnatal increase in the length of the loops of Henle results in more than doubling of the urine concentrating capacity by 3 weeks of age. Newborn infants have a shorter length of the loops of Henle and relatively short papillae that increase with maturation. The shorter loops of the superficial nephrons (that mature last) allow accumulation of urea in the inner medulla. With increasing maturation, their elongation into the deeper cortical and outer medullary portion, accompanied by the vascular bundles, correlates directly with an increase in concentration ability. In addition, the renal inner medullary tubular organization is also different in neonates and adults. The thin descending loop of Henle is less permeable to water but capable of actively absorbing Cl^- (the ClC-K1 and Na^+-K^+-Cl2 channels) without water in newborns, thus allowing for excretion of more dilute urine. The inner medullary duct is also incapable of recycling urea, as the urea transporters (UT-A1) are lower in the neonatal period. In addition to these anatomic and morphologic differences, the RBF is preferentially distributed to the renal medulla and the glomerular blood flow is greater in the deeper than the superficial nephrons. In contrast, in adults, 90% of the RBF is through the cortex, 10% is through the outer medulla, and only 1%–2% reaches the inner medulla and papillae: this allows adult kidneys to maintain osmotic gradient secondary to the countercurrent system.

In the fetus and newborn, urine is hypotonic compared with the serum. By term, the fetal urine output is almost 5 mL/kg/h. The diluting capacity of the immature kidneys is similar to those of adults, and both can excrete 10%–15% of a filtered load, but this is limited by the lower GFR in newborn infants, which limits the amount of water that can be excreted. The ability to excrete a water load is clearly seen by the fact that infants after a week of age are capable of producing urine with a specific gravity of 1.002 when the GFR increases. Even in preterm infants, urine flow rates increase rapidly after birth to more than half the adult levels (12–14 mL/min/1.73 m^2) and urine osmolality reaches adult levels (50 mOsm/kg).

Thus, while the fetal renal capacity to concentrate urine increases with gestation due to an increase in concentrations and tissue response to ADH, an increase in water reabsorption capacity in the collecting tubules occurs as a result of increasing AQP-2 expression. The decreased concentration capacity is also limited by the inability of the fetus to generate and maintain a hypertonic medulla and an adequate osmotic gradient. Fetal kidneys respond to hypervolemia, hypoxia, and asphyxia by alterations in concentrations of ADH that under adverse conditions limit transfer of water across the placenta, maintaining adequate blood volume and blood pressure.

Postnatal

In healthy newborn infants, the renal concentration capacity increases exponentially after birth and reaches adult levels by 2 years of age. The maximal urine concentration in term newborns increases from approximately 515 mOsm/kg in the first week of life to 800–900 mOsm/kg by 1 month and to more than 1100 mOsm/kg by 1 year of age. Even in preterm infants born at 30–35 weeks' gestation, DDAVP administration can produce urine of >500 mOsm/kg by 4–6 weeks of age, although some infants have been shown to do so within the first few days of water deprivation.

ACID–BASE REGULATION

The mature kidneys are capable of providing metabolic compensation for respiratory acidosis or alkalosis by modulating tubular excretion of H^+ (as NH_4^+ and other titrable acids) or increasing reabsorption of HCO_3^- (the predominant buffer in the extracellular fluid). Recent human data suggest that these compensatory mechanisms are not as immature as once assumed.

HCO_3^- is the predominant buffer in the extracellular fluid, is freely filtered in the glomerulus, and is reabsorbed almost completely throughout the length of the tubules. The proximal tubule has very low permeability to bicarbonate and chloride. Almost 80% of the filtered HCO_3^- is reabsorbed in the PCT, and about 10% in the TALH. The remaining 10% is absorbed via the distal tubules. As the HCO_3^- concentration in the tubules decreases, the concentration of Cl^- increases, producing a transepithelial chloride gradient and thereby favoring paracellular transport.[23] As much as 20% of the HCO_3^- is absorbed

passively from these paracellular pathways into the peritubular capillary network in mature kidneys, although this pathway is limited in neonates due to the low paracellular permeability for bicarbonate.

The mechanism of HCO_3^- reabsorption across the tubule is similar. At the level of the PCT, H^+ in the lumen combines with HCO_3^- to produce carbonic acid (H_2CO_3), which further dissociates into H_2O and CO_2 in the presence of carbonic anhydrase IV; the latter is absorbed by the AQP-1 gas channels. Once CO_2 is within the cell, carbonic anhydrase isoenzyme II converts CO_2 and H_2O back to H_2CO_3 to regenerate H^+ and HCO_3^-. HCO_3^- is transported across the basolateral membrane by the NBCe-1A (Na^+-$3HCO_3^-$) cotransporter in the proximal tubules and by the Cl^- exchanger (Cl^- HCO_3^-, AE1) in the collecting duct.[68] When secretion of H^+ in response to HCO_3^- reabsorption in the distal tubules results in an acidic pH below 6.4, additional H^+ excretion occurs as NH_4^+ and NaH_2PO_4 and is increased by aldosterone. Sodium and potassium concentrations, angiotensin II, PTH, and the extracellular fluid (ECF) status all affect tubular H^+ secretion. The ability of preterm infants born at 29 weeks to respond to an acid load is not fully developed until 3 weeks after birth.

The reabsorption of HCO_3^- is accompanied by equimolar secretion of H^+ into the tubular lumen by the NHE pump (NHE isoforms NHE-3 and NHE-2), which has a third of the activity rate of adults.[23] The secretion of H^+ in turn is regulated by the active extrusion of Na^+ from the basolateral membrane by the Na^+ K^+ ATPase to maintain a concentration gradient for Na^+. In addition, a vacuolar H^+ ATPase pump on the apical membrane contributes nearly one-third of the H^+ secretion in the proximal tubules.

In the distal tubules (collecting ducts), the secretion of H^+ facilitates HCO_3^- reabsorption by the intercalated cells. In the α-intercalated cells, H^+ ATPase and H^+ K^+ ATPase pumps on the apical membrane regulate H^+ secretion; the β-intercalated cells present in the cortical collecting duct, secrete HCO_3^- for Cl^- at the apical membrane (via the solute-linked carrier 26 [SLC26] isoforms),[69,70] and then extrude H^+ across the basolateral membrane via the H^+ ATPase pump.

Preterm infants have lower serum bicarbonate levels (16–20 mEq/L) than term infants (19–21 mEq/L) and adults (24–28 mEq/L) due to a lower renal threshold for HCO_3^-. The primary determinant of renal HCO_3^- threshold in preterm infants is the extracellular fluid status, not prematurity per se or the intrinsic tubular reabsorption capacity. When a HCO_3^- load is given in the presence of extracellular volume contraction, the HCO_3^- threshold and tubular reabsorption of HCO_3^- increase, thereby making the urine more acidic, and vice versa.[71] The limited reabsorption of bicarbonate in neonates is secondary to the limited activity of the NHE pump and active transport rather than passive back leak.[23] The increase in expression of NHE isoform with maturation (and with steroids and thyroid hormone) likely explains the higher plasma bicarbonate levels seen in more mature infants. Further, the absence of carbonic anhydrase isoenzymes limits the ability for HCO_3^- reabsorption in the proximal tubules, resulting in an increased delivery of HCO_3^- to the distal tubules, as seen with proximal renal tubular acidosis (RTA).

Urinary loss of bicarbonate in preterm infants persists until the readjustment of the ECF and maturation of the carbonic anhydrase system in the proximal tubules. The carbonic anhydrase system is functional by 24–26 weeks in the juxtamedullary nephrons, but not in the cortical nephrons until nephrogenesis is complete, by 34–36 weeks, and is at levels similar to those of adults at term. Clinically, the more immature infants show persistent metabolic acidosis that usually resolves by 2 weeks after birth. In animal models as well, postnatal maturation of the carbonic anhydrase system is enhanced by glucocorticoids and correlates with an increase in the tubular absorptive surface area and maturation of the NHE cotransporters. However, in humans, the role of glucocorticoids in this regard is not as well described.

Inherited forms of proximal RTA have been described with genetic mutations in the NBC-1 cotransporter (also known as solute-linked carrier SLC4A4), carbonic anhydrase II, and pyruvate carboxylase deficiency. Distal RTA has been described with mutations in AE1 (autosomal dominant) and the vacuolar H^+ ATPase (also called the ATP6V1-B1 subunit, autosomal recessive with sensorineural hearing loss) genes.

The kidneys also maintain acid–base homeostasis by excreting acid predominantly as ammonia. H^+ generated in the form of volatile (H_2CO_3_ excreted by lungs as CO_2) and fixed acids is initially buffered by HCO_3^- before being excreted predominantly as ammonium (NH_4^+). NH_3 is generated from glutamine in the proximal tubules, and both NH_3 and NH_4^+ are secreted into the lumen, mostly via the NHE-3 transporter (upregulated by metabolic acidosis), as well as NHE-3-independent channels.[72] The TALH reabsorbs the majority of luminal ammonia via the apical Na-K-2Cl transporter, resulting in an increase in medullary interstitial NH_3 concentrations. NH_3 diffuses into the collecting duct lumen, where it is buffered again to generate NH_4^+, which is then excreted in the urine. However, while acid excretion in the fetus is carried out by the placenta, tubular mechanisms for excreting an acid load are functional in the third trimester and newborn infants are able to excrete an acid load. The other titrable acid, NaH_2PO_4 generated from Na_2HPO_4, is also functional in newborn infants.

EFFECTS OF PRETERM BIRTH AND OLIGONEPHRONIA

Preterm kidneys with fewer functional nephrons have been linked to hypertension and renal dysfunction in adults despite data to suggest that renal growth occurs to compensate for reduced nephron mass at birth.[73]

Since nephrogenesis is not complete until 34–36 weeks' GA, it is also important to understand the effects on renal growth following birth at an earlier gestation, as the majority of nephrons are formed late in gestation. A decrease in radial glomerular counts and glomerular generations was noted in autopsy specimens of preterm compared with term infants.[74] Other studies have also shown that renal growth does not follow the same intrauterine patterns as growth following preterm birth. In a baboon

model, Sutherland et al. noted that although nephrogenesis continued following preterm birth, postnatal glomerular growth was likely to be abnormal.[75] In another study,[76] Sutherland et al. compared renal growth in postnatal autopsy specimens following preterm delivery and in gestational-matched fetal deaths. They noted accelerated renal maturation after preterm birth, with an increased number of glomerular generations (also correlated with body weight and kidney weight), a decreased width of nephrogenic zones, and more immature glomeruli, particularly in the outer cortex. The percentage of glomeruli in the immature stages also decreased with increasing postconceptional age. Of importance, compared with gestational-matched control, preterm kidneys had a greater percentage of morphologically abnormal glomeruli and a significantly larger cross-sectional area of the renal corpuscle, suggestive of renal hyperfiltration.[76]

In other conditions associated with loss of nephron mass, such as outflow track obstruction or multicystic dysplastic kidney resulting in nonfunctioning kidney early in gestation, there is a significant increase in the size and weight of the contralateral kidney, with adequate renal function suggesting that the single-nephron GFR is increased. However, the hyperfiltration has been linked with focal glomerular sclerosis and renal failure in adulthood. Intrauterine growth restriction (IUGR), due to either maternal, placental, or fetal reasons, results in a decrease in the number of nephrons at birth.[77,78] Low birth weight is also associated with a decrease in the number and volume of glomeruli at birth.[79,80] Maternal nutritional status and specific nutrient deficiencies (vitamin A), smoking and alcohol, and fetal exposure to medications such as ACE inhibitors and PGE inhibitors, steroids, and aminoglycosides have all been linked with a decrease in the number of glomeruli at birth.[81] The timing of nephron loss during development may affect later adaptation. For example, unilateral nephrectomy in neonatal but not adult rats impairs RBF autoregulation and salt-sensitive hypertension in adulthood.

SUMMARY

The fetal kidneys produce urine by modifying blood ultrafiltrate at the level of the glomerulus into urine by reabsorption and secretion of solutes. The fetal kidneys are fully functional in utero, although they are limited in their concentrating capacity and in their ability to fully excrete a solute load. Nephrogenesis is completed by 34–36 weeks' GA, and postnatal renal growth after this age occurs secondary to an increase in existing glomerular and tubule size, not number. Following preterm birth, functional maturation occurs within a few weeks irrespective of the severity of preterm birth.

CHAPTER 23

Cystic Kidney Disease

Roshan P. George and Larry A. Greenbaum

INTRODUCTION

Cyst formation is seen in a variety of kidney diseases (Table 23.1). Many of these diseases are genetically inherited, and many are associated with extrarenal manifestations. They are generally rare diseases, although a few are common enough to cause considerable pediatric morbidity and mortality. Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common human genetic diseases, but its manifestations are usually fairly subtle in pediatric patients. It does cause considerable morbidity for adults, and it is likely that future therapy of this disease will focus on the pediatric patient.

The last decades have witnessed considerable advances in our understanding of cystic kidney diseases. The defective gene or genes have been cloned in many of these diseases, and this has led to increased understanding of pathogenesis and clarified some important clinical issues. Such genetic studies have also provided opportunities for improved prenatal and postnatal diagnoses.

Identification of genes and proteins that are defective in the inherited cystic diseases has led to the discovery that most of these proteins are expressed in the primary cilium of renal epithelial cells.[1–3] Primary cilia are nonmotile sensory organelles that detect extracellular stimuli and are highly conserved through evolution.[4] Primary cilia have a crucial role in modulating differentiation, migration, and proliferation of tubular epithelium. Current evidence suggests that there may be a common pathway for cyst formation, potentially related to the role of primary cilia in signal transduction.[5,6] This has led to the designation of "ciliopathies" for this group of disorders.[7]

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

The incidence of autosomal recessive polycystic kidney disease (ARPKD) has been estimated to be from 1 in 6,000 to 1 in 55,000.[8,9] The true incidence may be higher due to undiagnosed fatal neonatal disease.[10] Since ADPKD can present in infancy and ARPKD can present in young adults, the designation ARPKD is more precise than the term *infantile polycystic kidney disease*. Both the liver and kidneys are affected in ARPKD, with significant variability in severity between patients. Clinically, the prognosis for patients with ARPKD continues to improve.

Genetics

ARPKD is a classic recessively inherited disorder, with unaffected heterozygote parents and a 25% risk of an affected child in subsequent pregnancies. All cases of ARPKD are due to a mutation in the polycystic kidney and hepatic disease 1 (*PKHD1*) gene, located on chromosome 6, which encodes the protein fibrocystin (also called polyductin).[11,12] Fibrocystin has been identified in the collecting duct and the thick ascending limb of the kidney and in the epithelial cells of the hepatic bile duct, expressed in the primary apical cilia.[2,13] There is a correlation between the type of mutation and the clinical presentation. Infants with two truncating mutations typically die as neonates, while the clinical presentation varies in children with at least one missense mutation.[14,15] The severity of ARPKD is usually similar among children within the same family, but there are examples of families where siblings have very different clinical manifestations.[15–18]

Pathology

The kidneys are enlarged bilaterally. This enlargement is usually fairly symmetrical, and the kidneys retain their reniform shape. Careful examination of the kidney capsule will often reveal opalescent dots, which are due to the termini of dilated collecting ducts below the kidney capsule (Figure 23.1). Grossly, the kidneys have a spongy appearance because of the cystic dilations of the collecting ducts.[19] Large cysts are unusual in infancy, although there is a gradual increase in cyst size over time.[20] The microscopic appearance is dominated by the dilated collecting ducts, which are perpendicular to the kidney surface (Figure 23.2). The cysts are lined with a normal-appearing single layer of cuboidal or columnar epithelium.[19] The glomeruli often appear normal in newborns. Over time, there is increased interstitial fibrosis and glomerular sclerosis.

These patients have the typical features of congenital hepatic fibrosis.[21] There is proliferation and dilation of bile ducts and fibrosis of portal tracts. The distal portal veins are small, providing a microscopic explanation for the presence of portal hypertension. The absence of hepatocyte destruction correlates with the preservation of liver function in most patients.[22]

Clinical Features

There is significant variability in the clinical features of ARPKD (Table 23.2). Antenatal ultrasound, demonstrating hyperechogenic, markedly enlarged kidneys with no identifiable cysts, can detect ARPKD by 24 weeks of gestation.[23] The majority of patients present during the first year of life, with a significant percentage presenting during the first month of life.[20,24–26] The most severely affected neonates can have some degree of Potter syndrome due to oligohydramnios. Along with abnormal facies and joint deformities, these children have respiratory compromise due to pulmonary hypoplasia. Volume overload from renal failure and poor diaphragm function secondary to the enlarged kidneys can also impair respiratory function. Respiratory failure is thus fairly common in neonates.[20,24–26] The importance of the mass effect of the enlarged kidneys has been confirmed by demonstrating improvement in respiratory function following unilateral nephrectomy.[27] Pneumothoraces are probably related to the hypoplasia and the high ventilatory settings that these infants require. Death due to respiratory failure can occur in the first few days of life.[24]

The kidneys in ARPKD are typically large at birth and often increase in size. This causes abdominal distention on physical examination, but also has additional important secondary consequences. By limiting diaphragm mobility, respiratory function is compromised, adding to the problems described above. In addition, the enlarged

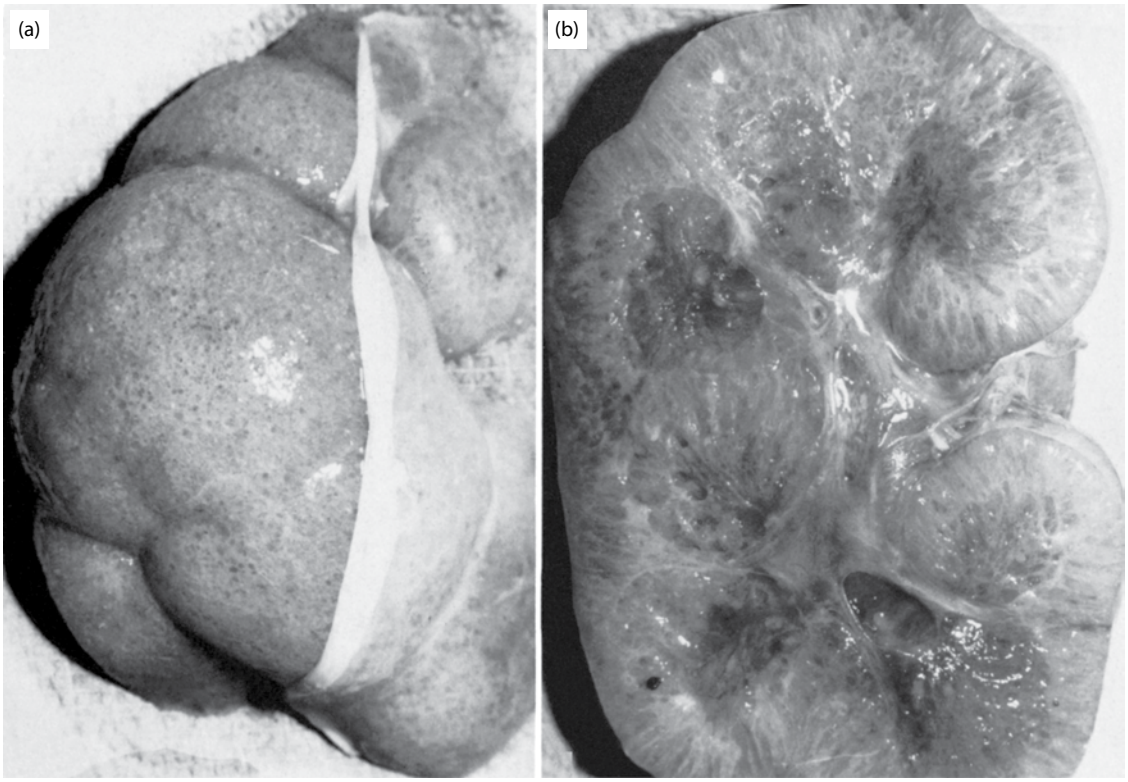

FIGURE 23.1 (a) Subcapsular surface of an ARPKD from a neonate. Innumerable small cysts can be seen beneath the capsule. (b) Cross section of the same kidney. The radial arrangement of the dilated ducts can be seen.

kidneys may impair gastric feeding[27] and patient mobility. It is important to note, however, that the kidney size can become less impressive over time in some patients, especially those who are receiving chronic dialysis.[20,28]

Chronic kidney disease and, ultimately, end-stage renal disease (ESRD) is the usual outcome in ARPKD. ESRD may be present at birth,[20,26] although it more typically develops gradually, with most children who survive the neonatal period not progressing to ESRD until later in childhood or even as young adults.[28,29] Many patients have some improvement in renal function during the first year of life, followed by a period of stabilization and subsequent decline.[30,31] This is probably secondary to the normal maturation of kidney function. More aggressive therapy in the newborn period might theoretically select for patients with more severe renal involvement, although neonatal presentation is not necessarily a marker for earlier progression to ESRD.[28]

Chronic kidney disease, especially untreated, is a potential cause of growth retardation. In addition, poor food intake, due to both renal failure and abdominal distention, may cause malnutrition. Not surprisingly, growth retardation is quite common in ARPKD,[20,32] and some children have severe growth retardation without a clear etiology.[28]

Hypertension is very common, probably due to fluid overload. This may be secondary to activation of the local renin–angiotensin system and increased sodium retention,[33] although two studies failed to demonstrate increased systemic renin or aldosterone levels.[24,28] Anywhere from 65% to 78% of patients require antihypertensive therapy.[9,24,26,28,31] The hypertension can be quite severe, causing severe morbidity[34] and even death.[24,28] Hypertension gradually diminishes in some children, and this may permit weaning of antihypertensive medications.[28]

There is an increased incidence of urinary tract infections (UTIs);[9,26,35] this may be related to vesicoureteral reflux (VUR) and catheterization,[36] and is more common in girls.[32,35] However, pyuria is often present in the absence of infection;[20] it appears to be less common in older children.[28] Proteinuria may be detected, often intermittently,[26,37] but it is not of sufficient magnitude to cause clinical problems. Gross hematuria is uncommon, but has been reported.[28]

Patients can have the typical electrolyte disturbances associated with renal failure, such as hyperkalemia and hyperphosphatemia. Acidosis develops with significant renal failure, but may be present earlier due to impairment in tubular acid excretion.[28,38] Patients almost always have a decreased ability to concentrate their urine,[26,28,38] and thus are at risk for dehydration and nocturnal enuresis. There is an increased risk of hyponatremia, which is most common in infants.[24,35]

Portal hypertension due to congenital hepatic fibrosis leads to a number of complications. The liver may be enlarged and spider nevi are sometimes visible.[26,28,32,36,39] Splenomegaly was present in 47% of patients over 3 months of age in one series,[24] and this increased to 60% in children over 1 year of age.[36] This can be associated with anemia and thrombocytopenia.[36,39] Esophageal varices can lead to problems with hematemesis;[39,40] variceal rupture can be fatal.[24,26,36] Dilated biliary ducts predispose children with ARPKD to develop cholangitis.[35,39] This can occur in the neonatal period, and it has been fatal in some children.[26] Hepatocyte damage does not occur, and synthetic function remains normal,[39,40] although mild abnormalities in liver enzymes are occasionally detected.[26,32] Overall, approximately 7% of patients surviving the neonatal period will eventually need liver transplantation for complications resulting from cholangitis and portal hypertension.[35]

Some patients initially have predominant liver involvement,[9,39] with kidney abnormalities discovered as an incidental radiographic finding. In fact, there are some adults

diagnosed with congenital hepatic fibrosis or Caroli's disease who have mutations in the *PKHD1* gene.[41] Other children have both severe liver and kidney disease at an early age.[28] A single-center retrospective review, looking at 133 patients between 1961 and 2004, indicated that patients diagnosed in infancy were more likely to have renal manifestations and secondary pulmonary insufficiency than patients presenting later in life, who showed more hepatic manifestations.[10] The hypothesis that severe liver disease predicts minimal renal involvement[42] is no longer accepted.[21]

It is possible that additional clinical features of ARPKD may be discovered as patients survive further into adulthood. For example, intracranial aneurysms were described in a 31-year-old patient with ARPKD.[43] While only a case report, this is especially intriguing given the presence of intracranial aneurysms in ADPKD.[44]

Radiologic Features

Intravenous pyelogram (IVP) shows enlarged kidneys with a delayed nephrogram (Figure 23.3).[45,46] Radial streaks due to contrast in the dilated collecting ducts are usually present in infancy, but may not be visible in older children.[25] Because of concerns regarding intravenous contrast, a renal ultrasound is now the usual frontline diagnostic test. Ultrasound shows enlarged kidneys with increased echogenicity and poor corticomedullary differentiation (Figure 23.4);[47,48] a hypoechoic rim is often visible.[49] Older children have increased medullary echogenicity, which may resemble nephrocalcinosis.[28] Reversal of corticomedullary differentiation has been reported; it is an important finding, as few other conditions cause reversed corticomedullary differentiation.[50] Multiple small cysts may be visible by ultrasound,[28,48] but this is quite variable (Figure 23.5). Macrocysts are sometimes visible in older children.[43,47,48,51]

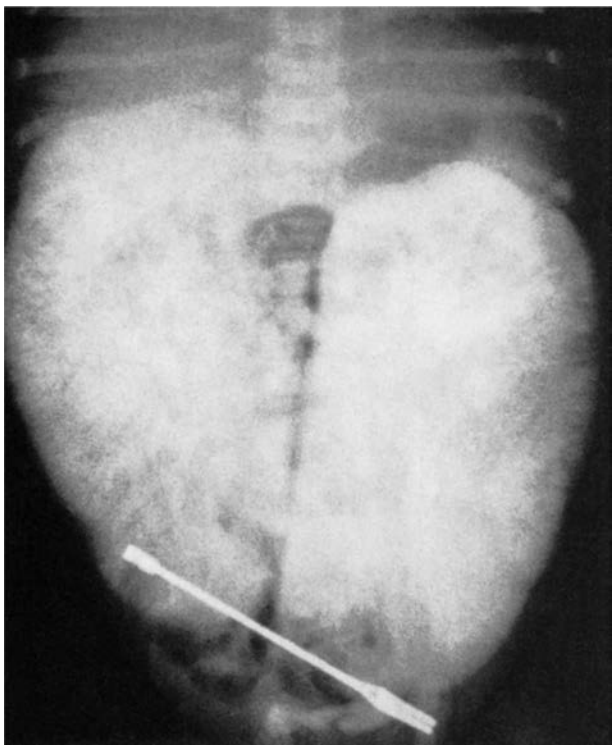

FIGURE 23.3 IVP from a 2-day-old girl with ARPKD. Notice the sunray appearance of the contrast material and the enormous renal size.

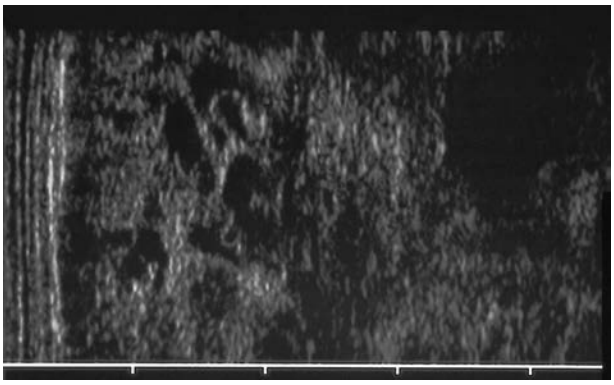

FIGURE 23.5 High-resolution renal ultrasound of the same patient shown in Figure 23.4. High-resolution cysts are seen, and the hypoechoic rim is still visible. (Courtesy of Dr. J. Sty, Children's Hospital of Wisconsin, Milwaukee.)

Ultrasound detects liver abnormalities in approximately 50% of patients.[28,35] It is often possible to detect dilations of the peripheral intrahepatic biliary ducts and the principal biliary duct. There may also be evidence of portal hypertension.[28] Magnetic resonance imaging (MRI) and computed tomography (CT) may provide better visualization of renal and hepatic findings in the setting of equivocal ultrasound results.[52]

Diagnosis

A large percentage of children are now diagnosed due to an abnormal prenatal ultrasound.[35] The presence of bilaterally enlarged kidneys during the first few years of life is suggestive of ARPKD. The radiologic features, as detailed above, can be helpful, but are not always conclusive. This

is especially true in older patients with ARPKD since cysts may be enlarged and thus resemble those seen in ADPKD.[43] It is important to investigate the family history; the presence of a sibling with ARPKD is obviously highly suggestive. Consideration must be given to an early presentation of ADPKD, and therefore it is now common to augment the family history with renal ultrasounds of the parents, and possibly the grandparents if the parents are young, to rule out this possibility. In one study, 6.7% of the patients with neonatally lethal polycystic kidney disease had ADPKD.[26] For inconclusive cases, histological examination of the liver is useful. Congenital hepatic fibrosis is always present in ARPKD and is extremely rare in ADPKD.[53,54] Liver ultrasound may also demonstrate hepatic disease.[28] Kidney biopsy is rarely performed because of concerns regarding the safety of the procedure in these children. In the histological evaluation of the kidney, the absence of glomerular cysts supports a diagnosis of ARPKD.

Genetic diagnosis is commercially available, but challenging because the *PKDH1* gene is extremely large and complex and the known mutations are quite heterogeneous.[15,41] Mutations are more likely to be detected in children with severe ARPKD than in children with moderate disease.[15,41]

Nephroblastomatosis and bilateral Wilms' tumor are part of the differential diagnosis of bilaterally enlarged kidneys. Transient nephromegaly of the newborn can be confused with ARPKD,[55] but this resolves relatively quickly. A variety of other diseases with renal involvement can also have hepatic manifestations. These include Meckel syndrome,[56] juvenile nephronophthisis (NPHP),[57] Ivemark syndrome,[58] Jeune syndrome,[59] COACH syndrome,[60] and Bardet–Biedl syndrome.[61]

Prenatal Diagnosis

Prenatal ultrasound often detects abnormalities in a fetus with ARPKD.[9,23,62–66] The kidneys may be hyperechoic[63] and increased in size.[64–66] Serial ultrasound showing inappropriate increases in kidney length improves diagnostic reliability.[23] In addition, some fetuses have oligohydramnios. However, a precise diagnosis is often impossible prenatally given the limits of current imaging and alternative diagnostic possibilities. Naturally, in a family with a previous child who has ARPKD, the clinical likelihood of this diagnosis is increased. Unfortunately, there have been cases of both false-positive and false-negative diagnoses.[63,67] False positives are especially likely in a fetus without a family history of ARPKD or if oligohydramnios is not present.[63] Conversely, in a family at risk, a normal prenatal ultrasound, especially before the third trimester, should not be used to predict an unaffected child.[18,66–68] Fetal MRI has also been used to diagnose ARPKD.[69]

As stated previously, mutation screening is difficult and not 100% sensitive.[15,41,70] Linkage analysis can determine if a fetus has ARPKD in families with a previous affected child.[71] This analysis requires preservation of DNA from the previous child. The clinical course of a previously affected child does not always predict the severity of the ARPKD in a subsequent child.[18,24] Parents clearly need genetic counseling regarding this possibility. Supplementing linkage analysis with prenatal imaging studies could theoretically aid in this discussion, but it is especially difficult to make outcome predictions based on the fetal ultrasound.[18]

Treatment

The initial management of respiratory distress is quite challenging. In the past, many of these children were presumed to have pulmonary hypoplasia, and thus therapy was limited. It is now clear that other factors contribute to the respiratory insufficiency. Both unilateral and bilateral nephrectomies, by decreasing the effect of abdominal distention, have been successfully used to improve respiratory function and allow children to wean from respiratory support.[27,72] Although providing a less dramatic decrease in abdominal distention, unilateral nephrectomy can be done without forcing the patient to undergo dialysis.[27] It is important to evaluate relative renal function before proceeding with a unilateral nephrectomy, lest the remaining kidney have limited function. Bilateral nephrectomies require that a peritoneal dialysis catheter be placed simultaneously; it is therefore recommended that the kidneys be removed extraperitoneally, with meticulous attention to the peritoneal membrane.[72]

Reversible causes of respiratory insufficiency, such as volume overload, persistent fetal circulation, hyaline membrane disease, infection, and pneumothoraces, should be treated before concluding that a patient has irreversible pulmonary failure. The use of more aggressive perinatal support strategies, such as surfactant, high-frequency oscillatory ventilation,[27] extracorporeal membrane oxygenation (ECMO), dialysis, and hemofiltration, may also decrease the mortality from respiratory failure.

The massively enlarged kidneys create a variety of problems beyond respiratory distress. Both unilateral and bilateral nephrectomies can have other benefits, such as improved tolerance of feedings[27] and increased activity in older children. Left nephrectomy, assuming equivalent renal size, may have more benefits for gastric function than a right nephrectomy.[27]

Hypertension should be aggressively treated, given that uncontrolled hypertension has been associated with severe complications and even death.[24] Hypertension frequently requires multiple medications,[35] and is often difficult to control,[9] leading to bilateral nephrectomy and the initiation of peritoneal dialysis in some children.[36] Interestingly, hypertension may sometimes lessen as the patient ages, allowing successful weaning of antihypertensive medications.[31,36]

Chronic kidney disease and ESRD are managed using the usual strategies. Patients are treated for electrolyte problems, anemia, and renal osteodystrophy. Tube feedings and growth hormone are often necessary to manage failure to thrive. Dialysis and, ultimately, transplantation are needed when the patient reaches ESRD. Both peritoneal dialysis and transplantation often require prior nephrectomies to create sufficient abdominal space.

Complications of portal hypertension need to be addressed.[73] Esophageal varices may require sclerotherapy or placement of a portacaval shunt,[39,74] with one patient receiving a shunt as early as 2 years of age.[24] Cholangitis

needs to be aggressively treated with antibiotics. Splenectomy has been performed in children with intractable hypersplenism that causes anemia and thrombocytopenia.[36] Liver transplantation is occasionally necessary.[35] Hepatic complications can cause significant morbidity and mortality after renal transplantation.[75]

Prognosis

ARPKD is associated with considerable morbidity and mortality. Improved therapy in the newborn intensive care unit and better treatment for chronic kidney disease is continually changing the long-term prognosis. Nevertheless, patients continue to die, with much of the mortality occurring in the first year of life, especially during the first month.[24,26,28,35] Respiratory failure and sepsis are currently the most common causes of death.[35] Neonatal ventilation is a strong predictor of mortality and the early development of chronic kidney disease.[35] Children who survive beyond the first month had a 5-year survival of 87% in a report of a North American registry.[35]

There is clearly significant long-term morbidity in these patients due to chronic kidney disease, systemic hypertension, and portal hypertension. However, patients are continuing to benefit from improvements in surgical and medical management.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD, with an incidence of 1:400 to 1:1000, is the most common inherited kidney disease. Although kidney involvement, with cystic dilation in all parts of the nephron, is the major feature for most patients, there are protean extrarenal manifestations, including the potentially life-threatening possibility of a ruptured intracranial aneurysm. Severity varies greatly between patients, and symptoms tend to develop over time. Fortunately, most children are asymptomatic; even middle-age adults may be unaware of their diagnosis. There are, however, some ADPKD patients who present with severe neonatal disease, which can have significant morbidity and can occasionally be fatal.[30] This underscores the importance of avoiding the term *adult polycystic kidney disease*.

An increasing percentage of children with ADPKD are diagnosed due to a positive family history or because of an incidental finding during an imaging study. This has caused a marked shift in the pediatric patient population, with many patients having no symptoms and requiring very limited intervention.

Genetics

ADPKD is a genetically heterogenous condition; disease occurs due to mutations in one of two genetic loci (Table 23.3). Patients with a mutation of the *PKD1* gene,[76] which is located on chromosome 16, account for the majority of cases. Most remaining cases are due to a mutation in the *PKD2* gene on chromosome 4.[77] While initial studies suggested that 15% of cases are due to *PKD2* mutations, it now appears that *PKD2* mutations cause a higher percentage of cases.[78]

TABLE 23.3 Gene defects causing ADPKD

Gene	Chromosome location	Protein
PKD1	16p	Polycystin
PKD2	4q	Polycystin 2

PKD1 encodes for a protein called polycystin 1, which is a transmembrane protein with multiple extracellular domains.[79] The *PKD2* gene product, polycystin 2, is also a transmembrane protein and has moderate homology to polycystin 1.[77] Polycystin 2 is a calcium-permeable, nonselective, cation channel that increases calcium permeability of the cell membrane.[80] Polycystin 1 and polycystin 2 interact with each other, and are localized within primary cilia.[81–83]

The variable development of cyst formation in ADPKD appears to be related to the need for a second inactivating mutation. The kidney cells of patients with the *PKD1* mutation initially have one normal allele for polycystin and one defective gene. Cyst formation occurs when there is a second somatic mutation that inactivates the normal gene. This produces a cell that does not produce any normal polycystin. Additional cysts are due to a second mutation in other cells.[84,85] A similar mechanism takes place in patients with *PKD2*.[86,87] This helps to explain why cysts appear fairly randomly and increase in number over time.

There is a great deal of variability in the severity of ADPKD. It is clear that some of this variability is based on the specific gene affected. Patients with *PKD2* have less severe symptoms, including later mean age for the development of ESRD and a decreased incidence of hypertension, UTIs, and hematuria.[88,89] In one study, the median age of death or onset of ESRD was 53 and 69 years in patients with *PKD1* and *PKD2*, respectively.[88] This difference in severity has been shown to be due to cysts forming earlier in *PKD1* patients; the rate of cyst growth, once formed, is similar in *PKD1* and *PKD2* patients.[90]

There is also evidence that the disease severity is influenced by the specific mutation (allelic heterogeneity) in the *PKD1* or *PKD2* genes.[91–93] Additional sources of variability may involve environmental factors and genetic differences at other loci.[94–96] For example, polymorphisms in the angiotensin-converting enzyme (ACE) gene modify renal disease severity in patients with *PKD1*.[97] In cases of neonatal ADPKD, the affected parents have not had early-onset disease.[26,98,99] However, there appears to be an increased likelihood of early disease in affected siblings[26,98,100,101] and other members of the same kindred.[99] Early-onset disease may be more likely in families with mutations in *PKD1*.[102]

Pathophysiology

The kidneys are typically enlarged and have random cysts, which can originate from any portion of the nephron (Figure 23.6). Except for cysts, the renal architecture is initially normal, although as the disease progresses, fibrosis and glomerulosclerosis gradually increase.

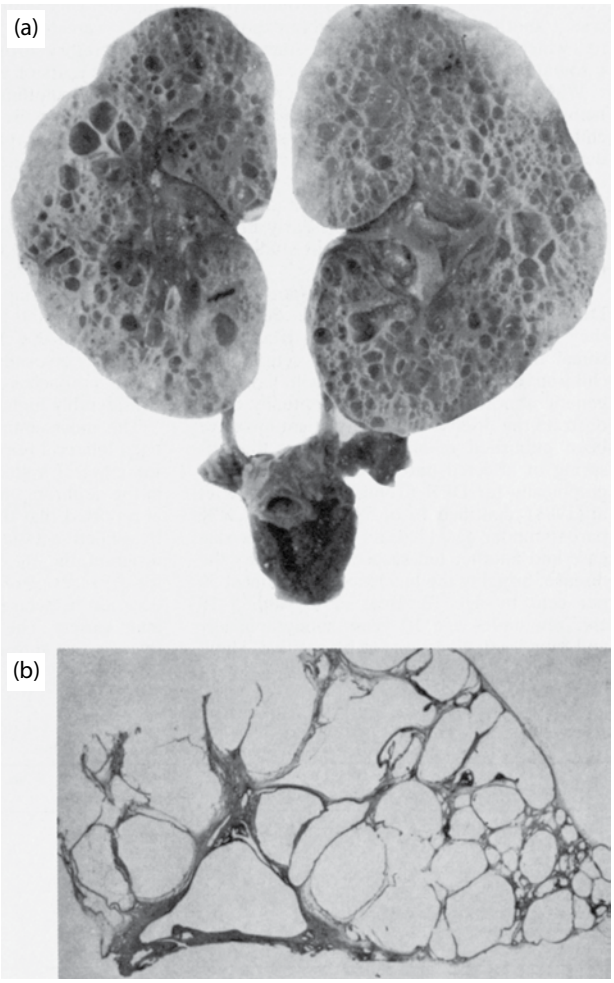

FIGURE 23.6 (a) Example of adult polycystic kidney disease in a 3-month-old. Notice the rounded cysts of varying size. (b) Low-power view of the same kidney. Foci of normal renal tissue are seen between the grossly dilated tubules. (Reproduced from Blyth H, Ockenden BG. *J Med Genet* 1971;8:257–84. With permission.)

In ADPKD, there is dysfunction of the primary cilia; it is a ciliopathy. Cilia are essential in maintaining cell polarity, a process that is important during cell division and proliferation.[103] Primary cilia are mechanosensors, converting mechanical signals such as fluid flow into a chemical signal within the cells, and are also involved in signal transduction of paracrine signals, such as Wnt, Sonic Hedgehog (Shh), and platelet-derived growth factor α.[103–106] In rodent models, the noncanonical Wnt and planar cell polarity signaling are important for the regulation of cell polarity during the development of the renal tubules. In ADPKD, there is abnormal signaling by the primary, and this causes misorientation of the mitotic spindle in relation to the longitudinal axis of the tubule, resulting in the formation of cysts.[107]

Cyclic adenosine monophosphate (cAMP) is a second messenger for multiple signaling pathways, and increased cAMP occurs in human ADPKD and animal models of polycystic kidney disease.[108] The V2 receptor (V2R), when activated, produces cAMP. In several animal models of cystic kidney disease, there is increased V2R activity and V2R antagonists slow cyst progression.[109] Other pathways and receptors implicated in the pathogenesis of cyst development include the epidermal growth factor family and its related receptors and the mammalian target of rapamycin (mTOR) pathway.[110–112]

Clinical Features

Most children with ADPKD are asymptomatic, and increasing numbers of these patients are diagnosed based on a positive family history, followed by a screening CT scan or ultrasound. Others are diagnosed after kidney cysts are incidentally noted on an imaging study, including prenatal ultrasound.

Although children are often asymptomatic, there are reports of severe disease, including neonatally lethal disease.[26,98,113] Neonatal mortality is usually due to respiratory failure and is associated with massively enlarged kidneys.[26,100,113] Most neonates diagnosed based on an abnormal prenatal ultrasound are asymptomatic. The majority of these children maintain normal renal function, but some will reach ESRD during childhood.[28,102,113,114] Maternal inheritance may be a risk factor for neonatal presentation.[115]

Most children with symptomatic ADPKD have a more subtle presenting complaint, typically in late childhood or adolescence.[26,28] Hematuria is quite common in adults with ADPKD[116] and can manifest in childhood.[26,28,117,118] Other presenting symptoms include hypertension, frequency, abdominal or flank pain, abdominal mass, UTI, and proteinuria (Table 23.4).[26,28,118,119] The majority of patients who are symptomatic during childhood do not have renal insufficiency as young adults,[28] but they may be at a higher risk for early kidney failure.[118]

The presence of symptoms in children correlates with the number of cysts. Children with more than 10 cysts have an increased incidence of flank or back pain, palpable kidneys, and hypertension.[119] Such children also have more complaints of palpitations and urinary frequency than their unaffected siblings.[119]

Hypertension and resultant end-organ damage occurs at an earlier age in children with ADPKD than in their healthy peers.[120] When a group of mostly asymptomatic children were screened, 13% had hypertension (vs. 0% of controls) and the hypertensive patients had left ventricular

hypertrophy.[121] A smaller study using ambulatory blood pressure monitoring found no evidence of hypertension in patients below 15 years, but there was an increase in left ventricular mass.[122] In addition, patients between 15 and 25 years had significant increases in blood pressure and ventricular mass.[122] In another study, a significant proportion of normotensive young adults with ADPKD were found to be prehypertensive with blunted "nocturnal dipping" on ambulatory blood pressure monitoring.[123] Another study found hypertension at clinical presentation in 22% of children.[115] Not surprisingly, hypertension is more common in children who are symptomatic in the neonatal period.[26] The renin–angiotensin system is implicated in hypertensive adults with ADPKD and normal renal function,[124] along with reduced renal blood flow and sodium retention,[125] although these mechanisms have not been studied in children.

Some children with mild ADPKD have a subtle defect in urinary concentrating ability,[28] and this is more common in children with more than 10 cysts,[119] along with an increased incidence of proteinuria.[126] Kidney stones, often presenting as acute flank pain, are increased in adults,[127] but are infrequent in children.

Kidney infections are more common in patients with ADPKD, and complications may include perinephric abscess, septicemia, and death;[128] there may be an increased risk of VUR.[129] Cyst infection is especially troublesome since the urine culture may be negative and not all antibiotics achieve therapeutic levels in the cyst fluid.[128]

There are a large number of possible extrarenal manifestations in adults with ADPKD (Table 23.5). Extrarenal involvement is less common in childhood. Mitral valve prolapse (MVP) is found in 26% of adults with ADPKD.[130] Among a group of children, 12% had MVP (vs. 3% of controls), and the incidence increased with age.[121] Inguinal hernias are substantially increased in both children[118,119] and adults.[131,132]

Cholangiocarcinoma
Congenital hepatic fibrosis

Liver cysts are the most common extrarenal manifestation in adults with ADPKD, with the prevalence increasing with age.[133,134] Women tend to have more and larger cysts;[135] pregnancy is an additional risk factor.[134] Some adults experience abdominal fullness and pain, but cysts almost never impair liver function or cause portal hypertension,[133,135] except in extreme cases.[136] Infected liver cysts present with pain, fever, and leukocytosis.[137] Liver cysts are rare in children,[119,138] but in a study of 230 patients between 15 and 46 years with ADPKD, MRI revealed an overall prevalence of hepatic cysts of 83%, and in the subgroup of patients from 15 to 24 years, the prevalence was 58%.[139] Liver enlargement[26] has occasionally been described in children.

Pancreatic cysts are present in only 9% of patients over 30 years of age,[140] and almost never cause complications;[141] they are extremely unusual in children.[138] The claim that ovarian cysts are increased in ADPKD has been questioned.[142] The remaining cystic complications are quite rare.[143]

Ruptured intracranial aneurysms are a significant cause of mortality in adults with ADPKD.[144] In one study, the mean age of bleeding was 39.5 years, but 10% of patients were less than 20 years.[145] There are reports of young children with a subarachnoid hemorrhage,[26] a bleeding arteriovenous malformation (AVM),[146] and ruptured intracranial aneurysms.[147,148] Aneurysms cluster in families,[149–151] and thus a positive family history for intracranial hemorrhage or aneurysm is an important risk factor.

Gender differences in ADPKD include the predisposition to liver cysts in women. The rate of progression to kidney failure is faster in adult males with either *PKD1*[152] or *PKD2*.[88] No gender differences among children have been reported.[119]

Radiologic Features

Ultrasound (Figure 23.7) and CT scan (Figure 23.8) are useful for detecting the macroscopic cysts of ADPKD. The number and size of cysts in children increase with age, and those children with more cysts have increased kidney size.[119] Increased renal echogenicity may be seen in some

FIGURE 23.7 Ultrasound of an infant with severe ADPKD. The kidneys are enlarged due to multiple cysts. (Courtesy of Dr. J. Sty, Children's Hospital of Wisconsin, Milwaukee.)

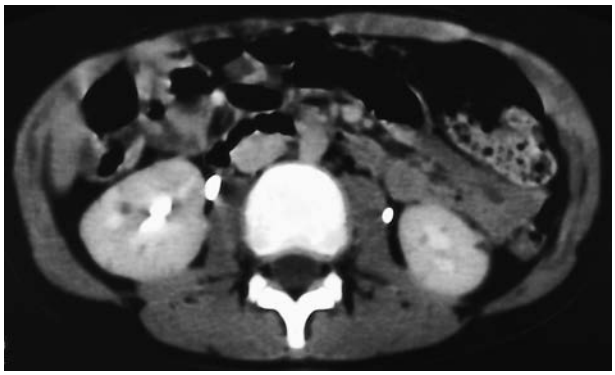

FIGURE 23.8 CT scan of a child with ADPKD. Macroscopic cysts are readily visible. (Courtesy of Dr. J. Sty, Children's Hospital of Wisconsin, Milwaukee.)

children.[48] Occasionally, children can have marked disease asymmetry, which can create diagnostic confusion.[153] Liver cysts are quite unusual in children.[119]

Diagnosis

Rare, early-onset ADPKD can sometimes be diagnosed by prenatal ultrasound,[98,99,154,155] although most cases are identified in the last 10 weeks of gestation. The kidneys are large, with increased echogenicity, and cannot easily be distinguished from the kidneys of children with ARPKD. Occasionally, macrocysts are identified.[154] Early diagnosis in a fetus with an affected parent is possible using DNA analysis.[156,157]

Even after birth, it is often difficult to distinguish early-onset ADPKD from ARPKD. Radiologic studies of the kidneys are often inconclusive. Liver imaging or biopsy is useful because hepatic fibrosis is always present in ARPKD. Kidney pathology is also helpful, given the absence of glomerular cysts in ARPKD. In ADPKD, cysts arise in every segment of the tubule and rapidly close off from its origin in the nephron. In ARPKD, by comparison, cysts are derived from the collecting tubule and remain connected to the nephron of origin. The presence of a parent with ADPKD is the most useful diagnostic clue. Yet, many parents are unaware of their own disease,[28,102] and thus screening imaging studies of "normal" parents are mandatory. Because of the possibility of a false-negative radiologic study, screening of the grandparents is sometimes useful, especially if the parents are less than 30 years old.

Diagnosis in asymptomatic or mildly symptomatic children is usually accomplished by renal ultrasound. The sensitivity and specificity of this approach increase with the child's age (Table 23.6). There are age-dependent ultrasound criteria for diagnosis.[158] It is important to note, however, that ultrasound cannot be used to exclude the diagnosis of ADPKD in asymptomatic patients younger than 40 years. Unilateral cysts may be the only initial finding in children with ADPKD,[28,119,147,153,159,160] and in the context of a positive family history, even a single cyst is highly suggestive of disease.[161] Bilateral cysts are frequently found on later investigation.[119] For adults, given the increased incidence of benign solitary cysts, more stringent criteria are necessary to avoid false positives.[162]

TABLE 23.6 Sensitivity and specificity of ultrasound for detecting ADPKD in children

Age	Specificity (%)	Sensitivity (%)
3 months–5 years	89	62
5 years–10 years	100	82
10 years–15 years	100	86
15 years–17.5 years	100	67

Note: This table summarizes the results of ultrasound screening in a group of children with *PKD1* by linkage analysis. The presence of a single cyst was interpreted as a positive ultrasound.

The ability to screen patients for mutations in the *PKD1* or *PKD2* genes is currently commercially available, although false-negative results can occur. Identifying a mutation in a known affected family member is useful for proving that a negative result is a true negative.

Treatment

A variety of interventions to slow the progression of ADPKD have been tested in animal models, and a phase III clinical trial of tolvaptan, a vasopressin 2 receptor antagonist, demonstrated a significantly slower increase in kidney volume than with placebo.[434] Tolvaptan has not been tested in children, and there is thus no recommendation to initiate tolvaptan in children. Moreover, since tolvaptan essentially causes nephrogenic diabetes insipidus, the massive polyuria may be a challenging side effect in children.

The mTOR inhibitor rapamycin was shown to stabilize cyst growth in a randomized crossover study (SIRENA) at 6 months,[163] but two larger randomized trials of mTOR inhibitors in adults with longer periods of follow-up did not show functional benefits with these agents.[164,165]

Children with severe disease receive standard therapy for chronic kidney disease. This should include careful monitoring of nutrition and growth. In adults with moderate renal insufficiency, there was no benefit to protein restriction, although there was a marginal slowing in the rate of glomerular filtration rate (GFR) decline in patients with severe renal insufficiency.[166] Such an approach is not recommended in children because the benefits are minimal and there is potential for adverse effects on growth and development.

Hypertension is fairly common in older children with ADPKD and should be treated. In adults with ADPKD, rigorous control of blood pressure was superior to standard control in reversing left ventricular hypertrophy.[167] There is not a consensus on the ideal class of antihypertensive agent to select for these patients. Despite the pathogenic role of the renin–angiotensin system,[124] and the evidence that ACE inhibitors slow the progression of renal insufficiency in a variety of kidney diseases,[168,169] ACE inhibitors, when rigorously tested, do not slow the progression of chronic kidney disease in ADPKD.[169] ACE inhibitors do reverse left ventricular hypertrophy in hypertensive adults with ADPKD,[170] but there is a small risk of precipitating acute renal failure in patients with ADPKD, and thus they

must be used cautiously.[171] Other agents, such as calcium channel blockers, have also been advocated.[172]

The goal of therapy is normalization of blood pressure using standard guidelines.[173] In adults with ADPKD, low targets for blood pressure may have a deleterious effect on renal function.[166]

UTIs should be treated promptly, with awareness for the increased risk of abscesses and septicemia. Cyst infection requires selection of an antibiotic that penetrates the cyst, such as trimethoprim-sulfamethoxazole[174] or ciprofloxacin;[175] occasionally, cyst aspiration may be necessary.[176] Patients with intractable pain from renal cysts can benefit from cyst aspiration, surgical reduction, or thoracoscopic denervation.[177,178] Very rarely, nephrectomy may be indicated for recurrent UTIs, intractable chronic pain, and significant hematuria requiring ongoing transfusions or to accommodate the allograft.[179]

The possibility of a ruptured intracranial aneurysm is a frightening, albeit rare complication in pediatric patients. The advisability of screening patients is currently debated. Magnetic resonance angiography (MRA) is a safe and sensitive approach for detecting an asymptomatic aneurysm.[149] However, there is a need to balance the safety and efficacy of surgical intervention with the risk of aneurysm rupture. One decision analysis supported screening a 20-year-old patient with ADPKD,[180] although others have suggested a less aggressive approach.[181,182] Because of the familial predilection to aneurysm formation,[149,150] screening of older teenagers with a positive family history is a reasonable approach.[183] However, patient selection and timing and frequency of screening continue to evolve.[184,185]

Prognosis

Most children with ADPKD have minimal symptoms throughout childhood. The adult course of the disease is extremely variable.

There are currently limited data on the ultimate prognosis for patients diagnosed during childhood. This is especially true for patients with asymptomatic cysts; the impact of increased numbers of cysts on the risk of chronic kidney disease is unknown. Children who are diagnosed after the neonatal period do not have a decrease in GFR, even in the subgroup with more cysts and symptoms.[119] In adults, the presence of the *PKD1* gene, younger age at diagnosis, male gender, hypertension, increased left ventricular mass, hepatic cysts in women, three or more pregnancies, gross hematuria, UTI in men, proteinuria, and renal volume are all independently associated with poor renal function.[152,186] In children, increased renal volume in early life or hypertension is associated with subsequent faster renal growth, a potential marker of a worse prognosis.[187] There seems to be a higher risk of early chronic kidney disease when patients have more severe disease as children.[118]

Interestingly, many children diagnosed antenatally have normal renal function,[28] although follow-up is relatively limited. The cases diagnosed neonatally frequently have severe, often fatal, disease. These children are at risk for early chronic renal insufficiency and ESRD. However, others maintain normal renal function throughout childhood.[102]

NEPHRONOPHTHISIS

NPHP, also called juvenile NPHP, is one of the most common causes of chronic kidney disease in children.[188] NPHP, which is recessively inherited, is often grouped with dominantly inherited medullary cystic disease because of an overlapping radiologic and histologic appearance. However, medullary cystic disease is genetically distinct, lacks extrarenal involvement, and usually presents in adulthood. We will therefore consider it separately later in this chapter.

Genetics

Mutations in 13 genes (*NPHP1–NPHP11*, *AHI1*, and *CC2D2A*) have been identified that cause NPHP (Table 23.7), and additional genetic heterogeneity is likely.[189–196] These genes encode components of the ciliary apparatus, composed of the primary cilia, basal bodies, or centrosomes.[197,198] Mutations in the *NPHP1* gene are the most common cause of NPHP.[199,200] Most patients with NPHP

TABLE 23.7 Genetic heterogeneity of NPHP

Type	Chromosome locations	Gene mutated	Encoded protein
NPH type 1	2q13	*NPHP1*	Nephrocystin
NPH type 2	9q22	*NPHP2*	Inversin
NPH type 3	3q22	*NPHP3*	Nephrocystin 3
NPH type 4	1p36	*NPHP4*	Nephrocystin 4
NPH type 5	3q21	*NPHP5*	Nephrocystin 5/IQCB1
NPH type 6	12q21	*NPHP6*	Nephrocystin 6/CEP290
NPH type 7	16p	*NPHP7*	GLIS2
NPH type 8	16q	*NPHP8*	RPGRIP1L
NPH type 9	17q11	*NPHP9*	NEK8

NPH type 11	8q22	*MKS3*	Meckelin
AHI1	6q23	*AHI1*	Jouberin/AHI1

type 1 are homozygous for a large deletion that affects the *NPHP1* gene.[199,201]

Pathology

Grossly, the kidneys are often small and have a pale, finely granular surface.[202,203] On light microscopy, there is diffuse interstitial fibrosis with a mononuclear cell infiltration.[202,204,205] Along with tubular atrophy, there is extreme thickening and lamination of the tubular basement membranes.[202,204] Electron microscopy confirms this thickening, and also shows splitting of the basement membrane.[202] Sudden variation from one histologic abnormality to another is highly suggestive of NPHP.[206] In a child with a biopsy early in the course of the disease, tubular basement membrane thickening was the only histologic abnormality.[205] Cysts appear to originate from the distal convoluted tubules and collecting ducts.[204] The glomeruli may be normal or have periglomerular fibrosis with thickening of Bowman's capsule; glomerular obsolescence eventually develops.[202]

Clinical Features

Polyuria and polydipsia are due to poor urinary concentrating ability, and this can lead to problems such as dehydration, nocturia, and primary or secondary nocturnal enuresis.[202,207,208] Renal sodium wasting[202] leads to salt craving in some children.[207] The urinalysis is notable for the absence of abnormalities,[202,203,207] although low levels of proteinuria, usually tubular in origin,[208] are sometimes present. Glucosuria is also occasionally present.[208,209] Probably due to the polyuria and salt wasting, hypertension is unusual,[203,210] except in patients with NPHP type 2. Symptoms of chronic kidney disease, such as fatigue, anorexia, and growth retardation, are frequently present.[203,207,208,211] Symptoms of renal osteodystrophy may be the initial complaint.[211] Children with NPHP have anemia that is out of proportion to their degree of renal failure, and thus often have very low hemoglobin levels and notable pallor.[203,207,208,211,212] The anemia appears to be due to decreased erythropoietin production.[213] Growth is decreased, initially due to chronic dehydration and later due to renal insufficiency. NPHP may be associated with liver fibrosis with development of hepatomegaly and portal fibrosis, which is different from the biliary dysgenesis seen in classic congenital hepatic fibrosis.[57] A mutation in the *NPHP3* gene was described in a patient with NPHP and liver fibrosis.[194]

The majority of patients with NPHP type 1 develop ESRD at a mean age of about 10–13 years.[202,214] The defect in urine concentrating ability can lead to severe dehydration and acute renal failure, which may accelerate the development of chronic kidney disease.[214]

NPHP type 2 is distinct from the other forms of NPHP. Renal failure occurs in infancy, and the kidneys are large with widespread cysts.[198,215] Hypertension is more common than in the other forms of NPHP. *NPHP2* gene defects may also lead to situs inversus in a minority of children.[198] The timing of ESRD is fairly similar in NPHP type 1 and NPHP type 4, while ESRD develops at about a mean age of 19 years in NPHP type 3.[214,216]

Based on the median age of onset of ESRD, the clinical variants are described as infantile (1 year of age), juvenile (13 years of age), and adolescent (19 years of age), with specific gene defects associated with each variant.[197] Infantile *NPHP* is associated with mutations in the *NPHP2* gene, leading to ESRD by 1–3 years. The juvenile form is the most common. Juvenile NPHP is most commonly due to *NPHP1* gene mutations. *NPHP3* gene mutations are common with the adolescent variant.[194]

Senior–Løken syndrome is the combination of NPHP with tapetoretinal degeneration,[217,218] and it is seen in 10%–15% of cases.[196] In the early-onset form, called congenital amaurosis of Leber, nystagmus is usually present, and there is an absent pupillary response to light. The retina is markedly abnormal on funduscopic examination; findings include arteriolar narrowing, pale optic discs, and granular pigmentation of the fundus.[219] Most patients are blind or severely visually impaired, and have a flat electroretinogram.[208] There is a late-onset form of Senior–Løken syndrome in which visual impairment develops during childhood. Moreover, patients with a defect in the *NPHP1* gene may have ocular findings, including areas of retinal atrophy with flat or low-voltage electroretinograms. However, these patients are usually asymptomatic, and probably should not be considered to have Senior–Løken syndrome.[210,220,221] Senior–Løken syndrome is most commonly seen in association with mutations of *NPHP5* and *NPHP6*, although it may occur with other genes.[222,223]

Some children with NPHP have other extrarenal manifestations, including mental retardation,[202,212,224] hepatic fibrosis,[202,224–227] Dandy–Walker syndrome,[212] cerebellar ataxia,[226,228] coloboma,[202] and skeletal anomalies.[202,226,228–230] However, there is some question about the rigor of the renal diagnosis in some of these cases.[231]

Mutations in the *NPHP1* gene have been associated with extrarenal manifestations, including Joubert syndrome,[232] ocular motor apraxia Cogan type,[233] and the combination of cerebellar ataxia and nystagmus.[234] Mutations in the *NPHP3* gene can cause hepatic fibrosis or tapetoretinal degeneration.[194] Mutations in the *NPHP4* gene can cause ocular motor apraxia Cogan type or tapetoretinal degeneration.[189,235] Mutations of *NPHP5*, *NPHP6*, and *NPHP10* genes are associated with retinitis pigmentosa.[236]

The more common possible extrarenal manifestations of NPHP are shown in Table 23.8. Many patients with extrarenal manifestations also have tapetoretinal degeneration, and thus are part of the Senior–Løken syndrome.

TABLE 23.8 Extrarenal manifestations in NPHP

Tapetoretinal degeneration
Liver fibrosis
Skeletal abnormalities
Mental retardation
Cerebellar ataxia
Situs inversus
Cardiac malformations

Other syndromes associated with NPHP include Jeune syndrome (asphyxiating thoracic dysplasia),[237] Ellis–van Creveld syndrome,[238] Alstrom syndrome (retinitis pigmentosa, deafness, obesity, and diabetes),[239] RHYNS syndrome (retinitis pigmentosa, hypopituitarism, NPHP, and skeletal dysplasia),[230] Bardet–Biedl syndrome (obesity, cognitive impairment, retinal dystrophy, microorchidism in males, polydactyly, and renal abnormalities),[240] Meckel–Gruber syndrome,[241] Mainzer–Saldino syndrome (NPHP with cone-shaped epiphyses of the phalanges),[228] and Arima syndrome (cerebro-oculo-hepato-renal syndrome).[242]

Radiologic Features

By ultrasound, the kidneys are hyperechoic with loss of corticomedullary differentiation; they are of normal or slightly decreased size.[243–245] Medullary cysts are a hallmark of the disease, but they are not always detected by ultrasound.[207,243,244] CT is a more sensitive method for identifying medullary cysts[246] and thin-section CT is recommended.[207]

Diagnosis

The diagnosis of NPHP can be challenging, especially in patients without extrarenal manifestations. A history of polyuria and polydipsia, salt craving, disproportionate anemia, a benign urinalysis, and the age of presentation are important clues. The detection of medullary cysts in the setting of chronic kidney disease in a child and smallish, echogenic kidneys is virtually diagnostic. The presence of consanguinity or an affected sibling suggests an autosomal recessive disease, and thus strongly supports the diagnosis. Renal histology is potentially helpful in uncertain cases. Genetic diagnosis is now possible and is commercially available, although the large number of genes, some not yet identified, limits sensitivity. All patients should have an ocular examination to screen for Senior–Løken syndrome and a liver ultrasound to screen for hepatic fibrosis.

Treatment

There is no specific therapy for NPHP. Families should be counseled regarding the risk of dehydration due to polyuria. The anemia responds to erythropoietin. Children receive standard therapy for chronic kidney disease and ultimately require dialysis and transplantation. The disease does not recur in the kidney transplant, and thus transplant is usually quite successful.[219,247] Appropriate specialist care is necessary in children with extrarenal manifestations.

MULTICYSTIC DYSPLASTIC KIDNEY

Multicystic dysplastic kidney (MCDK) is the most common cystic disease diagnosed during childhood. Most cases are unilateral and asymptomatic; rare bilateral disease is usually fatal at birth due to Potter syndrome.[248] The widespread use of prenatal ultrasound has led to more frequent diagnosis of MCDK, and the approach to the management of these patients is evolving.

The incidence of MCDK is estimated at 1 in 2500 newborns;[249] it is one of the most common fetal anomalies detected by prenatal ultrasound. It occurs slightly more commonly in the left kidney,[250] and the affected child is more likely to be male.[251,252] Given the low incidence of unilateral renal agenesis in neonates, and the much higher incidence of single kidneys in adults, the majority of adults with a single kidney had an MCDK that involuted over time.

MCDK is typically composed of cysts of varying size that do not appear to communicate, separated by a small amount of abnormal-appearing renal parenchyma. The ureter from the affected kidney is atretic. On microscopic examination, the tissue between the cysts is dysplastic, with undifferentiated mesenchymal cells, often with cartilage, and immature glomeruli and tubules. Occasionally, a few normal-appearing nephrons may be present, explaining the minimal renal function that is infrequently demonstrated on nuclear scan.

Most cases of MCDK are sporadic,[253] although families with putative autosomal dominant inheritance have been described.[253,254] The incidence of MCDK is increased in a variety of syndromes.[255] The pathogenesis of MCDK has been attributed to either early ureteral obstruction[256] or disruption of the normal mechanism of induction of the metanephric blastema by the ureteric bud.[257]

Currently, most MCDKs are diagnosed by prenatal ultrasound, with palpable abdominal mass, typically in the neonate, as the second most common presentation.[258–260] There are rare cases of diagnosis due to symptoms such as emesis or respiratory compromise from compressive effects.[261] In older children, MCDK is uncommonly diagnosed during the evaluation for abdominal pain or mass, hematuria, or hypertension. In all ages, MCDK may be discovered during the evaluation for UTI or as incidental finding during abdominal imaging.[262,263]

The diagnosis of MCDK is typically made by ultrasound. In infants with a prenatal diagnosis, a postnatal ultrasound should be performed to confirm the presence of MCDK. The major diagnostic dilemma is differentiation from hydronephrosis.[264] In MCDK, there is typically no communication between cysts, and the larger cysts are not medial. In hydronephrosis, the calyces extend outward from the dilated renal pelvis, and there is renal parenchyma surrounding the central cystic structure. The normal reniform shape is usually present with hydronephrosis, but usually absent in MCDK.[265] If the diagnosis is unclear, a radionuclide scan shows uptake of tracer if hydronephrosis is present, but usually no uptake with MCDK. Occasionally, MCDK demonstrates a small amount of uptake,[266,267] and other studies may then be useful in confirming the diagnosis.[264]

The contralateral kidney, if normal, undergoes compensatory hypertrophy, the absence of which suggests abnormalities of the contralateral kidneys.[268] Children with MCDK are more likely to have abnormalities of the contralateral kidney.[251,269,270] VUR has been reported in 4%–31% of contralateral kidneys,[250,251,269–271] with a majority of the patients showing a VUR of grade III or below.[272] Other reported anomalies include ureteropelvic

junction obstruction, ureteral ectopia, ureterovesical junction obstruction, ureteroceles, and renal dysplasia.[251,269,270]

The natural history of MCDK is usually gradual involution. The rate of involution is greatest in the first 2 or 3 years of life.[273] In one study, 18% were undetectable by ultrasound at 1 year of age, and 58% were undetectable by 6 years of age.[258] Some MCDKs do increase in size during the first few years of life, and complete involution may take more than 20 years.

Hypertension, which is postulated to be renin mediated,[274] has been reported as a potential complication of MCDK.[250,275] There are reports of hypertension being cured following surgical removal of the MCDK.[274] Yet, others have questioned the validity of these reports. For example, in a series of 260 cases, there were only 4 patients with hypertension, which was described as minimal and probably unrelated to the MCDK.[276] A more recent systemic review of 29 studies including 1115 patients found just 6 cases of hypertension, an incidence lower than that found in the general pediatric population.[277]

Malignancy is another possible complication of MCDK. There are cases of Wilms' tumor in younger children[278] and renal cell carcinoma in older teenagers and adults,[279] but some question the validity of these reports.[280] The true increase in risk is unclear. Less than 0.1% of the 7500 children enrolled in the National Wilms Tumor Study Group had an MCDK.[280] A recent systematic review concluded that the risk of malignancy is extremely low.[281]

The management of MCDK is controversial.[275,282,283] There has been a shift from routine surgical removal to nonoperative management, consisting of surveillance ultrasounds to monitor normal compensatory hypertrophy of the contralateral kidney and possibly to screen for Wilms' tumor.[276] There is not a consensus on the frequency of these ultrasound evaluations, especially given the low risk of Wilms' tumor. Ultrasounds are usually done more frequently during the first year of life (e.g., every 6 months), and then less frequently (e.g., every 12 months) until approximately age 5 years.[258] Surgical removal (discussed in Chapter 28) is indicated if there is any change that is suspicious for a Wilms' tumor. Other indications for nephrectomy include mass effect, pain, hypertension, and parental preference.

Follow-up, and surgical repair when indicated,[251] of the contralateral kidney is also critical. The follow-up ultrasounds of the MCDK should evaluate the size and echogenicity of the contralateral kidney; there should be compensatory hypertrophy.[250,270] Given the high rate of VUR, routine voiding cystourethrogram was frequently recommended,[284] although this has been questioned in the child with a normal-appearing contralateral kidney.[251,285] Routine monitoring of blood pressure, urinalysis to detect proteinuria, and follow-up of renal function, especially in the child with an abnormal contralateral kidney and potential risk for the development of chronic kidney disease, is recommended.[286]

MEDULLARY CYSTIC KIDNEY DISEASE

Medullary cystic kidney disease (MCKD) is frequently grouped with NPHP as the juvenile NPHP–medullary cystic disease complex.[287] However, MCKD is clearly a distinct entity, based on its autosomal dominant inheritance and later onset.[288] Renal failure typically develops during adulthood, although renal insufficiency may be apparent in some children.[235,288,289] In some families, the disease is not apparent until a mean age of more than 60 years.[290] Hyperuricemia and gouty arthritis, occasionally diagnosed in childhood,[289] may be the presenting manifestation.[291,292] Other clinical features include polyuria, anemia, and hypertension.[293,294] The kidneys are usually of normal size or small, and renal imaging may show a few medullary cysts, but the absence of visible cysts is relatively common.[289] The urinalysis is typically benign, except for low-grade proteinuria in a minority of patients.[293] Histologic examination demonstrates interstitial nephritis; thickening and splitting of the basement membrane is the most notable feature.[289,295]

MCKD is classified into four types, based on the underlying genetic mutations. Mutations in *UMOD*, the gene encoding uromodulin (also called the Tamm–Horsfall protein), cause MCKD type 2, and are present in the majority of cases.[296,297] Mutations in *UMOD* also cause the autosomal dominant disorder, familial juvenile hyperuricemic nephropathy (FJHN), and uromodulin-associated kidney disease (UAKD).[296,298] It is now clear that MCKD type 2 and FJHN are the same, since they are genetically allelic and clinically indistinguishable.[289,296,299] The dominant features are chronic kidney disease and gout.[295] Genetic diagnosis, by sequencing of exons 3 and 4, the site of most mutations in this disorder, is commercially available.

The locus for MCKD type 1 has been identified on chromosome 1.[290] These patients tend to have fewer manifestations of hyperuricemia than patients with MCKD type 2 and a later onset of renal insufficiency.[293] There is evidence for additional genetic heterogeneity.[293,300] Mutations in the REN gene, which encodes renin, have also been identified as a cause of MCKD.[301] Some families with MCKD have been identified without mutations in *UMOD*, *REN*, or the gene on chromosome 1, but with a new locus linked to chromosome 2.[302]

Treatment includes management of hyperuricemia with xanthine oxidase inhibitor (allopurinol). Patients also receive standard management of chronic kidney disease.

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney (MSK) is predominantly a disease of adults, but it occasionally presents in childhood.[303–305] The intrapapillary collecting ducts are dilated, and multiple small cysts may be present. Not all renal pyramids are always affected, providing an explanation for the often asymmetric and focal appearance. This does not appear to be an inherited disease, although a few family clusters are described.[306,307]

The diagnosis of MSK is usually incidental, but it can be identified based on the characteristic changes on IVP, which shows stagnation of contrast in one or more renal papillae due to dilation of the collecting ducts (Figure 23.9). The resultant image has been described as a "pyramidal blush."[308] These changes are sometimes misdiagnosed as

FIGURE 23.9 IVP demonstrating bilateral MSKs in a 9-year-old girl who presented with hematuria. Note the characteristic radial stretching and puddling, which represent the contrast-filled dilated collecting tubules in this disease. (Adapted from Glassberg KI et al. Congenital anomalies of kidney, ureter and bladder. In Goldsmith HS, Karafin L, Kendall AR, eds., *Goldsmith's Practice of Surgery: Urology*. Hagerstown, MD: Harper & Row 1982, 1–82.)

papillary necrosis.[306] CT scan is not as sensitive for making the diagnosis of MSK, but it has a superior ability to detect the papillary calcifications that frequently complicate MSK.[304,309,310] Ultrasound also frequently detects this nephrocalcinosis, which may not be visible on a plain film.[304]

Clinically, patients are at increased risk for hematuria, UTI, and nephrolithiasis. There may be impairment of urinary concentrating ability[304] or urinary acidification (renal tubular acidosis [RTA]), but the GFR is normal.[311,312] The urinary concentrating defect can lead to complaints of polyuria in a child.[304] The increased risk of nephrolithiasis and nephrocalcinosis[313–315] is probably secondary to stagnation in the dilated collecting tubules and an increased incidence of hypercalcuria,[316] hypocitraturia, and hypomagnesuria.[317,318] Patients with RTA are more likely to have hypercalcuria or hypocitraturia, and the acidification defect may be the primary problem.[316,317,319] Nevertheless, even patients without a defect in urinary ion excretion have an increased risk of nephrolithiasis,[315] arguing for a role of the dilated tubules.[320]

The RTA in MSK, when present in a child, can lead to growth retardation.[305] RTA is sometimes associated with severe potassium wasting, and this can lead to symptomatic hypokalemia.[321]

Hematuria is usually mild, but massive bleeding is occasionally seen.[322] More commonly, MSK is the explanation for asymptomatic microscopic or gross hematuria, and these are frequent complaints in pediatric cases.[303,304]

The increased risk of UTI may be related to stasis in the dilated tubules and the presence of stones, which may cause obstruction or act as a nidus of infection. UTI in MSK is occasionally complicated by abscess formation.[323] A decrease in bone mineral density was also observed in young adults with MSK disease, and improvement was seen with potassium citrate therapy, according to one study.[324]

Associated anomalies reported with MSK include hemihypertrophy,[305,325–329] Caroli's disease,[330,331] hyperparathyroidism,[332,333] and a variety of miscellaneous disorders.[307,334,335]

Most patients require limited treatment. Nephrolithiasis is successfully treated by the usual approaches, including extracorporeal shock wave lithotripsy.[336] The plasma creatinine generally remains normal, but a stone-induced obstruction may cause a rise in creatinine. Patients with MSK and RTA have a good response to alkali therapy, with decreased hypercalcuria and stone formation.[316,337] UTIs are treated conventionally, with the caveat that an abscess should be suspected if the patient does not respond.[323]

GLOMERULOCYSTIC KIDNEY DISEASE

Glomerular cysts are present in a variety of diseases (Table 23.9); the diagnosis is made by kidney biopsy. The term *glomerulocystic kidney disease* (GCKD) is reserved for patients who do not have an underlying disease, such as ADPKD. Typically, these patients have cysts involving less than 5% of nephrons without associated tubular dilation. As detailed below, GCKD is not a uniform, well-defined entity; rather, it describes a heterogenous group of patients who have been grouped into categories based on apparent inheritance and kidney size.

Glomerular cysts may be seen in children with a variety of severe, usually inherited, malformation syndromes (Table 23.9).[338–345] Many of these patients have accompanying renal dysplasia. Again, these patients have glomerular cysts, but they do not have GCKD.

Glomerular cysts are seen in ADPKD, but most patients also have cysts involving other segments of the nephron.[146,346,347] However, there are cases of GCKD in children with a strong family history of ADPKD.[100,348] This suggests that in these patients, GCKD is a variant of ADPKD, with predominance of glomerular cysts. In fact, one child had GCKD on initial biopsy, but subsequently had pathologic findings consistent with ADPKD.[348] It has also been hypothesized that some patients with "sporadic" GCKD may, in fact, have ADPKD, either due to a new mutation or because of incomplete family studies.

TABLE 23.9 Diseases with glomerular cysts

Syndromes with glomerular cysts
Brachymesomelia–renal syndrome
Oral-facial-digital syndrome
Glutaric acidemia type II
Trisomy 18
Renal retinal dysplasia
Short-rib polydactyly syndrome type II
Tuberous sclerosis
Zellweger syndrome
Autosomal dominant polycystic kidney disease
Sporadic glomerulocystic kidney disease
Familial hypoplastic glomerulocystic kidney disease
Autosomal dominant glomerulocystic kidney disease

Children with sporadic GCKD have a variable presentation. The kidneys are frequently enlarged at birth, with a loss of corticomedullary differentiation.[349,350] Kidney size may normalize,[350] and occasionally the medulla is of normal echogenicity despite an echogenic cortex.[349] Ultrasound and MRI can identify cortical cysts.[49,351] Renal function may be normal[349,350] or decreased.[352,353] Other cases of sporadic GCKD present in adults; these patients may have mild[65,354] or severe[355–357] renal failure, typically with enlarged kidneys.

There is an autosomal dominant form of GCKD that is associated with small (hypoplastic) kidneys and malformed or absent calyces.[358,359] These children have a decreased GFR at birth, but then renal function remains fairly stable. Some of these patients have been growth retarded,[359] and a few have a noticeable prognathism.[358,359] In some families, hypoplastic GCKD is secondary to mutations in hepatocyte nuclear factor 1β (HNF-1β).[360–363] Heterozygous mutations in HNF-1β may also cause maturity-onset diabetes of the young (MODY), and thus affected patients may have renal disease and diabetes.[360–362] This combination is often referred to as renal cysts and diabetes (RCAD) syndrome. Other extrarenal symptoms, such as hypomagnesemia, hyperuricemia, increased liver enzymes, and genital anomalies, may be present with this syndrome.[364]

The remaining families with GCKD have normal or increased kidney size. In one family with apparent autosomal dominant inheritance, kidney size and kidney function are normal, but those affected have an abnormal ultrasound.[365] In another family, a 10-year-old girl with an affected father has a mildly depressed GFR.[366] Melnick et al.[367] describe three siblings and their father; all have normal kidney size but a decreased GFR. Finally, a large family with GCKD was extensively studied by Sharp and colleagues.[368] These patients have hypertension, and renal function ranges from normal to ESRD. The kidneys are large and echogenic; pelvocaliectasis and a hypoechoic cortical rim are additional sonographic features. Inheritance is autosomal dominant, and linkage analysis indicates that neither the *PKD1* gene nor the *PKD2* gene is responsible for this family's disease.[368]

SIMPLE RENAL CYSTS

The increased use of radiologic testing has led to the identification of more children with simple cysts, which may be solitary or multiple. The incidence of simple cysts increases with age.[369–372] Less than 0.3% of children have simple renal cysts, and they are usually not associated with subsequent problems.[373] Cysts in children usually do not increase in size, and single cysts are commonly located in the right upper pole.[373] However, the presence of even a single cyst in the context of an appropriate family history supports a diagnosis of ADPKD.[161] The incidence of simple renal cysts is increased in children with AIDS.[374] Simple renal cysts are rarely detected by fetal ultrasonography, and the majority resolve before delivery.[375]

Simple renal cysts do not impair renal function,[373,376] except in rare instances.[377] They may play a role in causing infection[378] or hypertension[370,377,379,380] in some patients. Cysts in children occasionally cause pain.[381,382] Symptomatic cysts can be treated by percutaneous drainage, although they usually recur unless a sclerosing agent is injected. Injection of the cyst with either alcohol[383,384] or tetracycline[381] prevents recurrence. Surgical marsupialization is rarely necessary. Because cysts frequently occur in the upper pole, it is sometimes difficult to differentiate a cyst from upper-pole hydronephrosis due to an obstructed ureterocele or an ectopic ureter. Such a diagnostic dilemma can be resolved by cyst aspiration.[381,385] Cyst fluid has the same blood urea nitrogen (BUN) and creatinine concentration as the patient.[385] In adults, the Bosniak renal cyst classification, based on CT findings, categorizes cysts into four categories, distinguishing benign cysts from cysts with the potential to be malignant.[386] This classification, although not validated in children, was used in a single-center study where 39 children were retrospectively identified (from 1996 to 2004) based on a modified Bosniak classification, to have complex renal cysts. Of the five children in whom surgical resection was performed, three revealed benign cysts, but the other two had renal cell carcinoma.[387] Most children with simple renal cysts only need routine ultrasound follow-up, unless the cysts are atypical and therefore suggestive of a malignancy.

MULTILOCULAR CYSTS

A multilocular cyst is a unilateral, benign tumor of the kidney. Approximately half the cases occur in children, with the remainder in middle-aged adults.[388] Children are more likely to be male, while adults are more likely to be female. Children are usually less than 2 years of age, and the most common presenting complaint is an abdominal mass.[388,389] Pathologically, the multilocular cyst is well encapsulated and noninfiltrating. The multiple cysts, which do not communicate, are typically separated by fibrous tissue, although embryonic tissue is sometimes present, especially in pediatric cases. The cysts are well visualized by CT scan or ultrasound. The differential diagnosis includes Wilms' tumor, ADPKD, or an MCDK. Occasionally, a second multilocular cyst appears months later in the contralateral kidney.[390]

Because of the possibility of a cystic Wilms' tumor, surgical resection is recommended.[388] Nephrectomy is sometimes the only option, but increasing numbers of cases are managed with renal-preserving surgery.[388,390]

ACQUIRED CYSTIC KIDNEY DISEASE

Kidney failure is sometimes associated with cyst formation in a previously noncystic kidney. Acquired cystic kidney disease (ACKD) occurs in patients with renal failure, including dialysis patients, transplant patients, and chronic kidney disease patients. ACKD occurs in children, and the number of cysts increases over time.[391–395] Acquired renal cysts are also common in children who have undergone liver transplantation.[396] In one case series, treatment with cyclosporine in these hepatic transplant patients was identified as the only independent risk factor.[397] Children with ACKD are at a low risk for gross hematuria and

retroperitoneal hemorrhage.[392] More ominously, a small percentage of children develop renal cell carcinoma.[393,395] Because of this possibility, periodic ultrasound screening of dialysis patients is necessary and children with suspicious lesions should have a nephrectomy.

SYNDROMES WITH CYSTIC KIDNEYS

A large number of syndromes are associated with cystic kidneys. These are mostly rare diseases, and many are neonatally fatal. We briefly review the major features of a few prominent entities, emphasizing those with a defined genetic etiology.

Tuberous Sclerosis

Although classified as one of the neurocutaneous syndromes, renal involvement is an important cause of morbidity and mortality in tuberous sclerosis (TS).[398,399] Patients with TS develop hamartomas in a variety of organs, including angiomyolipomas of the kidneys. The major extrarenal manifestations of TS are summarized in Table 23.10. Most of the features of TS become more prominent over time, except for cardiac rhabdomyomas, which tend to regress during childhood.[400] The hypopigmented macules (ash-leaf spots) are especially helpful diagnostically since they are often visible at birth and are eventually present in more than 97% of children;[401] use of a Wood's lamp, especially in light-skinned individuals, may aid in their identification. Facial angiofibromas, which may be confused with acne, and Shagreen patches are also extremely common. Neurologic lesions include multiple calcified tubers, disorders of neuron migration, and giant cell astrocytomas. The neurologic manifestations, with both seizures and developmental delay, are often the dominant clinical feature. Tumors of the kidney are the most common cause of malignancy in TS, but a variety of extrarenal cancers are also seen in adults and children.[402,403]

TABLE 23.10 Extrarenal manifestations in TS

Neurologic
Cortical tubers
Seizures

Forehead fibrous plaque
Periungual fibromas
Confetti-like macules
Cardiac
Rhabdomyomas
Wolf–Parkinson–White syndrome
Bone
Sclerosis
Cystic changes
Pulmonary lymphangiomyomatosis

TS is an autosomal dominant condition, but two-thirds of the cases are due to new mutations, so most patients will not have a positive family history. There is variable penetrance, and thus affected parents usually have mild disease and may be undiagnosed. TS is caused by mutations in either the *TSC1* gene on chromosome 9[404] or the *TSC2* gene on chromosome 16.[405] Both of these genes encode tumor suppressors, and the hamartomas arise because of mutations in the normal wild-type gene.[406,407] Intellectual disability is more common in patients with mutations in the *TSC2* gene.[408,409] The *TSC2* gene is located adjacent to the *PKD1* gene on chromosome 16.[79] Some children have large chromosomal deletions that affect both the *TSC2* gene and the *PKD1* gene, and these children tend to have severe polycystic kidney disease.[79,410] This contiguous gene syndrome is present in the majority of children with early, severe polycystic kidney disease and TS.[411]

Angiomyolipomas are the most common renal lesion in TS and are readily seen by CT or ultrasound (Figure 23.10). Angiomyolipomas are usually not detected in the first few years of life, but they are ultimately found in most children with TS and they tend to increase in size during childhood.[412,413] Larger angiomyolipomas are sometimes associated with pain.[399] Hematuria is uncommon.[414] However, retroperitoneal bleeding from angiomyolipomas can be life threatening[398] and presents with sudden flank pain, a palpable abdominal mass, and symptoms of anemia. Clinical manifestations of angiomyolipomas are relatively uncommon in children.[415,416] In a study of 149 patients with TS, with the majority showing angiomyolipoma on ultrasound, only 19 gave a history of flank pain or hematuria on detailed surveys. This study also showed that the larger lesions (>3 cm) had increased risk for bleeding, but most patients remained asymptomatic.[417]

FIGURE 23.11 Renal CT of a child with cysts due to TS. Multiple cysts are visible. (Courtesy of Dr. J. Sty, Children's Hospital of Wisconsin, Milwaukee.)

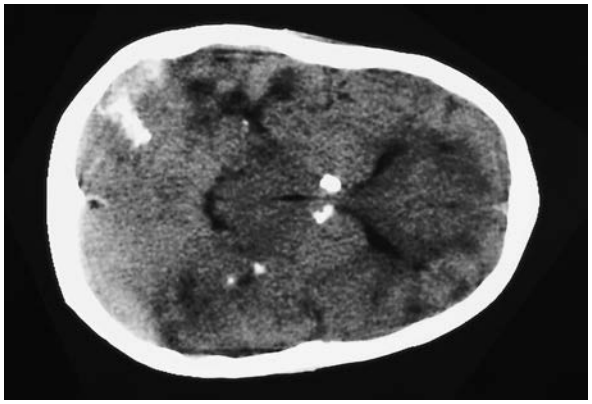

FIGURE 23.12 Head CT of the same child shown in Figure 23.11. Subendymal calcific densities are present in the region of the foramen magnum. (Courtesy of Dr. J. Sty, Children's Hospital of Wisconsin, Milwaukee.)

Renal cysts (Figure 23.11) are less common than angiomyolipomas and sometimes disappear on subsequent evaluation.[412] Renal malignancies, including renal cell carcinoma and malignant angiomyolipomas, are a serious concern in TS, and both are seen in children, sometimes in early childhood.[402,412]

Both renal cysts and angiomyolipomas cause destruction of normal renal tissue, and this can lead to renal failure in adults[418] and children.[411] The risk of renal failure and hypertension is greater in patients with cystic disease.[419–421] Children with disruption of the contiguous *PKD1* and *TSC2* genes usually have severe cystic disease and are at high risk for hypertension and early kidney failure.[411]

The diagnosis of TS is based on the classic clinical features, although genetic testing is commercially available. The possibility of TS should be suspected in a young child with large renal cysts suggestive of early-onset ADPKD. These children may have the contiguous gene syndrome with a deletion affecting both the *PKD1* and *TSC2* genes. A family history of TS is often not present due to variable penetrance and a high rate of new mutations. A search for skin manifestations is usually helpful, although cutaneous manifestations are less prominent or sometimes absent in infants.[401] Young children have fewer cortical tubers than older patients, but MRI is quite sensitive for detecting other subtle findings in infancy.[422] While MRI is more sensitive, most children have the mineralized subendymal nodules that are visible by CT (Figure 23.12).

Children with TS require the input of multiple specialists. All children with TS should have a renal ultrasound at diagnosis and follow-up renal ultrasounds every 1–3 years, with frequency dictated by the specific clinical situation.[423] Patients with extensive or rapidly changing lesions require more frequent follow-up. Those with more severe kidney disease may require CT or MRI to screen for malignant changes. Differentiating angiomyolipomas from malignancy requires careful comparison of sequential images. Patients with kidney failure are treated with dialysis[418] and transplantation.[424] Because of the risk for renal hemorrhage and malignancy, there is an argument for bilateral nephrectomies in children who progress to ESRD, especially those with large angiomyolipomas.

Meckel Syndrome

Meckel syndrome, sometimes called Meckel–Gruber syndrome, is a lethal autosomal recessive disorder. The most common extrarenal manifestations are posterior encephalocele, polydactyly, and hepatic fibrosis and cysts; however, a variety of other findings may also be present.[425,426] Cystic dysplasia of the kidneys is present in all cases.[425,426] Multiple genetic loci for Meckel syndrome have been identified.[241,427–429]

von Hippel–Lindau Disease

von Hippel–Lindau (VHL) disease is a rare autosomal dominant disorder with variable penetrance. The most prevalent manifestations are cerebellar hemangioblastoma, retinal angioma, pancreatic cysts, renal cell carcinoma, spinal hemangioblastoma, and pheochromocytoma.[430,431] Renal cysts are also common, but like renal cell carcinoma, they are rarely seen in childhood.[430,431] A mutation in a tumor suppressor gene, located on chromosome 3, causes VHL;[432] genetic testing is commercially available.

CHAPTER 24

Acute Kidney Injury

Lawrence Copelovitch

INTRODUCTION

Acute kidney injury (AKI), previously referred to as acute renal failure, is defined as a sudden decrease in kidney function that compromises the normal renal regulation of fluid, electrolyte, and acid–base homeostasis. In practical terms, AKI is characterized by a reduction in the glomerular filtration rate (GFR), which results in an abrupt increase in the concentrations of serum creatinine and blood urea nitrogen (BUN).[1] In 2002, the Acute Dialysis Quality Initiative Group introduced the RIFLE (acronym for risk for renal dysfunction, injury to the kidney, failure of kidney function, loss of kidney function, and end-stage renal disease) criteria in order to stage AKI. RIFLE aimed to standardize the definition of AKI by stratifying patients based on changes in the serum creatinine levels from baseline and/or an abrupt decrease in urine output.[2] The RIFLE criteria were found to be independent predictors of length of stay, costs, morbidity, and mortality in adults.[3] Subsequently, a modified pediatric RIFLE, or pRIFLE, was developed to stage AKI in children (Table 24.1).[4]

As highlighted by the RIFLE criteria, the urine volume in AKI is variable: patients may be anuric, oliguric, and in some cases, polyuric. AKI develops over a period of hours to days, whereas chronic kidney disease (CKD) develops over months to years. Short stature, renal osteodystrophy, delayed puberty, normocytic anemia, and hyperparathyroidism all suggest long-standing and advanced CKD rather than AKI. However, at a single point in time in an acute clinical presentation, it may be difficult to differentiate AKI from CKD without imaging studies, more extensive laboratory testing for the complications listed above, and possibly a kidney biopsy. Furthermore, at the time of presentation, a patient with CKD may have superimposed AKI, referred to as acute on chronic kidney disease.

AKI is usually encountered in pediatric urological patients as a complication of underlying chronic renal disease. The three most important contexts are acute pyelonephritis, aminoglycosides toxicity, and acute obstructive uropathy. Urologists must be alert to the possibility of AKI in any patient referred with bloody hematuria. The three most important contexts are urinary tract infection, glomerulonephritis, and myoglobinuria. Extracorporeal shock wave lithotripsy (ESWL) is the urologic treatment of choice for the majority of patients with renal or proximal ureteral stones.[5] Although rarely, bilateral or unilateral ESWL has been reported to be associated with AKI even in the absence of obstruction.[6] In order to most effectively diagnose the underlying cause of and treat the metabolic complications associated with AKI, all patients should undergo a full evaluation by a pediatric nephrologist at the time of presentation.

The likelihood of recovery from and appropriate treatment of AKI depends on the amount of urine output and the underlying cause. Quantifying the urine output is essential, as the amount of urine will often predict the clinical course and may aid in identifying the underlying renal insult. Patients with nonoliguric or high-output AKI (Table 24.2) have lower complication rates and higher survival than those with anuric or oliguric AKI.[7] Furthermore, children with acute interstitial nephritis or nephrotoxic renal insults, including aminoglycoside nephrotoxicity, are more likely to have AKI associated with either normal or increased urine output. In contrast, children with renal hypoperfusion injury, acute glomerulonephritis (AGN), hemolytic uremic syndrome (HUS), or other causes are more likely to have AKI associated with anuria or oliguria. The underlying cause of AKI may be classified as prerenal injury, intrinsic renal disease, or postrenal injury. It is important to note that some cases

TABLE 24.1 pRIFLE criteria

	Estimated GFR (eGFR)	Urine output
Risk	eGFR decreased by 25%	<0.5 mL/kg/h for 8 hours
Injury	eGFR decreased by 50%	<0.5 mL/kg/h for 16 hours
Failure	eGFR decreased by 75% or eGFR of <35 mL/min/1.73 m^2	<0.3 mL/kg/h for 24 hours or anuric for 12 hours
Loss	Persistent failure of >4 weeks	
End stage	End-stage renal disease (>3 months)

TABLE 24.2 Causes of nonoliguric AKI

Furosemide converting oliguric renal injury to nonoliguric renal injury
Nephrotoxins
Nonfulminant acute viral hepatitis
Primary lymphoma of the kidney
Severe exertional rhabdomyolysis
Hemolytic uremic syndrome

of AKI may be multifactorial, especially in hospitalized children.

PRERENAL INJURY

In prerenal AKI, renal function may be initially normal, but severe and/or prolonged renal hypoperfusion leads to renal injury and AKI. Prerenal AKI results from renal hypoperfusion caused by intravascular volume contraction, decreased effective circulating blood volume, or altered intrarenal hemodynamics. True intravascular volume contraction results from dehydration, acute blood loss, or extravascular accumulation of fluid—the so-called third spacing of fluid. This is most often encountered in patients with the systemic inflammatory response syndrome or with hypoalbuminemia. Infants are particularly vulnerable to excessive volume loss. They have a proportionally higher percentage of insensible water losses and, in addition, cannot maximally concentrate their urine as a result of immature kidneys. Decreased effective blood circulation occurs when the true blood volume is normal or increased, but renal perfusion is decreased. This commonly occurs in left-sided heart failure, cardiac tamponade, or hepatorenal syndrome.[8] Intrarenal afferent arteriolar vasoconstriction occurs in hepatorenal syndrome, calcineurin toxicity, and nonsteroidal anti-inflammatory drug (NSAID) use; intrarenal efferent arteriolar vasodilation occurs with the use of angiotensin-converting enzyme inhibitors (ACEIs). Afferent arteriolar vasoconstriction or efferent arteriolar vasodilation decreases the glomerular filtration.

In prerenal AKI, the kidneys are intrinsically normal and the reduced GFR and urine output are appropriate physiologic responses to the reduced renal blood flow. In the early stages, restoration of renal perfusion results in a prompt return of renal function to normal. If the insult is prolonged, acute tubular necrosis (ATN) may develop and the AKI will not immediately correct with improved renal perfusion. This signifies the progression to intrinsic renal disease. The evolution from prerenal injury to intrinsic renal disease is a gradual process because there are a number of compensatory mechanisms that maintain adequate renal perfusion. The two primary mediators of the intrarenal compensatory mechanism are the prostaglandins (PGI_2, PGE_2, and PGD_2) and angiotensin II. The prostaglandins promote compensatory vasodilation of the glomerular afferent arterioles in an attempt to maintain adequate blood flow and preclude further deterioration of renal function.[9] Angiotensin II causes a preferential constriction of the glomerular efferent arterioles, which increases glomerular filtration pressure.[10] The dilation of the afferent arteriole and constriction of the efferent arteriole work in concert to promote an increased filtration fraction and thereby maintain the GFR. Furthermore, angiotensin II, through direct action on the proximal tubule and through the effect of aldosterone on the distal tubule, causes increased sodium and water reabsorption. This helps to maintain an appropriate intravascular volume at the expense of a decreased urine output.

INTRINSIC RENAL DISEASE

When AKI is the result of intrinsic renal pathology, attempts are made to define the location of the insult. Renal injury may occur at the level of the renal vasculature, tubules, interstitium, or glomeruli. The basic mechanisms of renal injury include hypoperfusion, ischemic cell damage, toxin-mediated cell injury, and inflammation. The inevitable outcome is varying degrees of cellular death as a result of necrosis or apoptosis.[11]

Vascular Injury

Vascular injury may occur in large vessels, such as in renal artery thrombosis and renal venous thrombosis (RVT), or in the microvasculature, as in HUS and thrombotic thrombocytopenic purpura (TTP). Both renal artery thrombosis and RVT occur most commonly in newborn infants, while HUS is most common in young children. Conversely, TTP is rarely seen in pediatrics. Renal artery thrombosis is often associated with umbilical artery catheters and may result in hypertension. AKI rarely occurs unless there is a solitary kidney or the thrombosis is bilateral. In newborns, RVT is associated with maternal diabetes, polycythemia, and sepsis. Coagulation defects are increasingly being identified in neonates with RVT. In childhood, RVT is more closely associated with severe dehydration, nephrotic syndrome, and congenital hypercoagulable states.[12] RVT may present with large palpable kidneys, gross hematuria, hypertension, or oliguria. The neonate with RVT is usually very ill, but the condition may also be clinically silent.

The classic triad seen in HUS is acute hemolytic anemia with fragmented erythrocytes, thrombocytopenia, and AKI. The illness is usually preceded by an episode of acute gastroenteritis, often accompanied by bloody diarrhea. Sudden onset of pallor usually develops several days after the diarrheal illness resolves. Oliguria is a common feature, and one clue to making an early diagnosis is that the urine output remains decreased even with appropriate rehydration. The condition is usually caused by *Escherichia coli* O157:H7, a Shiga toxin–producing strain. The Shiga toxin is directly toxic to the glomerular vascular endothelium, where it initiates local coagulation (thrombotic microangiopathy), and to renal tubules, where it induces ATN. Several other strains of *E. coli*, as well as *Shigella dysenteriae* and *Aeromonas*, produce similar toxins that cause HUS. Non-diarrhea-associated HUS is a much less common condition caused by *Streptococcus pneumoniae* infections. Additional causes include bone marrow transplantation, HIV

infection, and medications. Inherited causes include deficiencies of factor H, factor I, and membrane cofactor protein (CD46).

Glomerular Injury

AGN is common in school-aged children but rare in children under the age of 2 years. Postinfectious glomerulonephritis is the most common cause in childhood. Antiglomerular basement membrane (GBM) antibody disease, anti-neutrophil cytoplasmic antibody (ANCA)-positive (pauci-immune) glomerulonephritis, lupus nephritis, immunoglobulin A (IgA) nephropathy, Henoch–Sconlein purpura nephritis, and membranoproliferative glomerulonephritis all cause AKI.[11] The clinical features of AGN include hypertension, oliguria, painless cola-colored gross hematuria, and edema that is more often periorbital than pedal; laboratory findings include proteinuria, red blood cell (RBC) casts, an increased serum creatinine concentration, evidence of antecedent streptococcal infection, and a low-serum-complement C3 concentration. Glomerular hypercellularity and inflammation result in a decreased GFR, reduced urine output, retention of potassium, and signs of fluid overload. The tubules and interstitium are mostly spared during the inflammatory process. Each of the glomerulonephritides can progress rapidly (rapidly progressive glomerulonephritis [RPGN]); this is characterized by oligoanuria, rapidly rising serum creatinine, and extensive crescent formation on renal biopsy. A diagnosis of RPGN must be made as soon as possible because treatment with corticosteroids, often together with plasmapheresis, is essential in order to preserve renal function.

Tubular Injury

Tubular injury is also known as ATN and is the end result of either ischemic or toxin-mediated damage to the tubules. The tubular epithelial cells are particularly sensitive to anoxia and are vulnerable to toxins. The cells of the straight segment of the proximal tubule and the thick ascending limb of the loop of Henle are highly dependent on oxidative phosphorylation. This serves to maintain their high energy demand, which is required for their transport functions. As a result, they are particularly susceptible to ischemia and to nephrotoxins that disrupt energy supply or mitochondrial function.[13]

Ischemia-induced ATN is the result of renal hypoperfusion. If the insult is prolonged and severe, prerenal AKI may progress to ATN that is no longer immediately reversible with restoration of appropriate renal perfusion. Tubular epithelium damage results in the release of vasoactive compounds that increase afferent arteriolar resistance, thereby decreasing renal blood flow and perpetuating tubular injury. This process is known as tubuloglomerular feedback and plays an important role in the progression from renal hypoperfusion to tubular injury. The vasoconstriction is exacerbated by adrenergic stimulation, decreased intrarenal prostaglandin synthesis, and increased angiotensin II formation.[11] The decrease in GFR is further reduced by the intraluminal tubular obstruction caused by the debris formed from sloughing tubular cells as they undergo apoptosis. The denuded tubular epithelium allows tubular back-leak of glomerular filtrate into the medullary interstitium, where it is returned to the systemic circulation. Tubuloglomerular feedback, intraluminal tubular obstruction, and tubular back-leak are all interrelated in the complex pathogenesis of AKI.[14] Several other vasoactive compounds, including endothelin and nitric oxide, are implicated in the progression of AKI, but their roles are not fully elucidated.

The clinical course of ischemia-induced ATN is divided into the anticipation phase, initiating phase, maintenance phase, and recovery phase.[15] During the initiating phase, the only signs might be a slight decrease in urine output and a rise in serum creatinine concentration and BUN. The maintenance phase is characterized by oliguria, fluid overload, acidosis, hyperkalemia, and a more rapid decline in GFR, usually with oliguria or anuria. Polyuria in the context of increasing serum creatinine concentrations is known as nonoliguric AKI. The recovery phase is characterized by polyuria, kaliuresis, and hypokalemia, while the serum creatinine and BUN begin to return to normal. The recovery process may take weeks to months, and more subtle impairments of tubular function may persist for even longer. If the ATN is prolonged and severe, the child may develop cortical necrosis, which is often associated with only partial recovery of renal function.

Toxin-mediated ATN can be caused by many medications (Table 24.3), poisons, or endogenous toxins. Common nephrotoxic medications are aminoglycosides, amphotericin, acyclovir, cisplatin, and radiocontrast agents.[11]

Aminoglycoside nephrotoxicity occurs in 10%–26% of patients,[16] usually after 1 week of treatment, although the AKI may be delayed until after discontinuation of the medication. The renal injury usually presents with a decrease in urine concentrating capacity, and is usually transient, mild, and nonoliguric. Serum and urine electrolyte abnormalities range from combinations of hypokalemia, hypomagnesemia, and hypocalcemia to complete acquired Fanconi syndrome or an acquired Bartter syndrome.[16,17] Accumulation of aminoglycosides in the lysosomes of the proximal tubules induces cell necrosis and the excretion of low-molecular-weight proteins (beta$_2$-microglobulin) and brush border enzymes. Risk factors for aminoglycoside-induced AKI are old age, hypovolemia, preexisting renal insufficiency, multiple nephrotoxic agents, hypokalemia, hypomagenesemia, prolonged use, total lifetime exposure, and elevated peak and trough levels.[11,14] It is important to note that studies in humans are dogged by confounding variables of the critically ill, and that the choice of an aminoglycoside should not be governed by nephrological

TABLE 24.3 Nephrotoxins

Diethylene glycol	Paraquat

criteria; the dosing, however, must be adjusted for the level of GFR. In most cases, there is full recovery with no evidence of permanent kidney disease or CKD.

Patients with amphotericin B–induced renal injury often present with nonoliguric AKI. Amphotericin B injures many different nephron segments, as well as the collecting duct. In addition to toxin-mediated AKI, amphotericin B may also cause hypokalemia and hypomagnesemia. Distal renal tubular acidosis occurs as a result of back-leakage of hydrogen ions into the interstitium.[11] Risk factors for the development of AKI include maximal daily dose, duration of therapy, and concomitant use of calcineurin inhibitors. Acyclovir-induced AKI is usually nonoliguric and may present with microscopic hematuria. Acyclovir is relatively insoluble in urine and, by forming crystals within the renal tubule, causes intratubular obstruction and a reduced GFR. Risk factors for the development of AKI include high doses, rapid intravenous administration, hypovolemia, and preexisting renal disease.[11]

Radiocontrast-induced nephropathy is uncommon in children and is usually mild and transient. The pathogenesis is unclear. Risk factors for contrast nephropathy include underlying renal disease, dehydration, large doses of contrast media, congestive heart failure, diabetes mellitus, and use of NSAIDs and ACEIs.[14]

Poison-mediated ATN may occur from direct tubular toxicity, as in mercury poisoning, or from crystal formation, as in ethylene glycol and methanol poisoning. Both ethylene glycol and methanol are nontoxic until they are metabolized by alcohol dehydrogenase into their metabolites. Once their metabolites have been generated, crystals will form in the tubules, causing obstruction and AKI.[11]

Endogenous toxins that can cause ATN are myoglobin, hemoglobin, and uric acid. Pigment-induced ATN can be precipitated by either hemoglobinuria or myoglobinuria. Tubular injury results from the precipitation of pigment in the tubules and heme protein–induced oxidative stress.[14] Myoglobin- or hemoglobin-induced AKI is more likely to develop in the presence of dehydration, metabolic acidosis, severe muscle damage, or multiple organ failure. Rhabdomyolysis is caused by viral infections (influenza), medications (statins), seizures, prolonged exercise, or illicit drug use (Table 24.4). The diagnosis can be confirmed by an elevated serum creatine phosphokinase level. The association between cocaine and rhabdomyolysis has been widely reported, while the association with amphetamines has only been described in case reports. Cocaine appears to have direct toxic effects on skeletal muscle, as well as vasoconstrictive properties, which lead to muscle ischemia.[18] Several proposed mechanisms have been put forth to explain methamphetamine-induced rhabdomyolysis, although direct myocyte toxicity has never been demonstrated. Amphetamine users are often agitated and experience uncontrolled choreiform movements. The rhabdomyolysis might occur in a fashion similar to that of exertional rhabdomyolysis after exhaustive physical exercise.[18,19] Hemolysis occurs in sickle cell disease, immune-mediated hemolysis, or glucose 6-phosphate dehydrogenase (G6PD) deficiency.[14]

TABLE 24.4 Causes of rhabdomyolysis

Chronic and inflammatory myopathy	Muscular dystrophy
Metabolic myopathy	Trauma
Nonketotic hyperosmolar coma	Exercise
Viral myositis	Dystonia
Malignant hyperthermia	Cocaine/methamphetamine ingestion

Treatment of pigment-induced AKI includes volume expansion, forced diuresis with a loop diuretic, and alkalinization of the urine to increase pigment solubility.[11] An increasing serum creatinine concentration in the context of fluid overload is an indication for hemodialysis.

Tumor lysis syndrome can be caused by excessive release of uric acid, phosphorus, and cell products, usually during treatment of acute lymphocytic leukemia or B-cell lymphoma. The probable mechanism of injury is related to precipitation of uric acid crystals in the tubules with obstruction of urine flow. The highest risk for tumor lysis syndrome is with the most rapidly growing tumors or during induction chemotherapy.

Aggressive hydration with the administration of allopurinol helps to decrease the uric acid burden and the risk of tubular precipitation. Rasburicase (urate oxidase) is an effective alternative to allopurinol for rapidly reducing uric acid levels, improving patients' electrolyte status, and reversing AKI. Screening for G6PD deficiency is essential prior to rasburicase administration, as it may cause hemolytic anemia and methemoglobinemia in susceptible patients.[20] Dialysis may be necessary if the metabolic abnormalities cannot be controlled with the aforementioned medical management.

Interstitial

Interstitial nephritis most often occurs as a result of exposure to medications. It can also be the result of infections, systemic diseases, tumor infiltrates, or genetic conditions. In many cases, no cause is found. Medications commonly associated with interstitial nephritis include extended-spectrum penicillins, NSAIDs, sulfonamides, and rifampin. Almost every known medication has been implicated. The pathogenesis of medication-induced acute interstitial nephritis is thought to be a hypersensitivity type or allergic reaction that causes an inflammatory reaction, mainly in the medullary interstitium. Many patients are asymptomatic or have vague complaints. Typical symptoms include fever, rash, arthralgias, and flank pain. Urine output is usually increased or normal because this is the most frequent cause of nonoliguric AKI. It is important to note that interstitial nephritis does not present with gross hematuria or isolated microscopic hematuria, and the urine may be bland, or there may be combinations of microscopic hematuria, mild proteinuria, pyuria, white blood cell (WBC) casts, eosinophilluria, and peripheral eosinophillia. Acute pyelonephritis, Epstein–Barr virus (EBV), and cytomegalovirus (CMV) also cause interstitial nephritis. Sarcoidosis and tubulointerstitial nephritis uveitis (TINU) are rare causes.

Postrenal Injury

Congenital obstructive uropathies are among the most frequent causes of CKD in pediatrics; this is often erroneously referred to as AKI when the presentation is in the newborn child. AKI rarely is the result of postrenal obstruction outside, except when this occurs in solitary kidneys from either aplasia or transplantation. In pediatric individuals with two functioning kidneys, postrenal AKI will occur only with urethral obstruction, bladder neck obstruction, or bilateral ureteric obstruction because a single normal kidney has sufficient ability to maintain a normal GFR. Most patients with acute obstruction leading to AKI have oliguric AKI, although nonoliguric AKI can occur with partial obstruction. Renal calculi, ureteral blood clots, retroperitoneal fibrosis, neurogenic bladder, bladder tumors, and urethral strictures can cause an obstruction at different levels of the urinary tract and lead to AKI.[14] During acute obstruction, a decreased GFR is the result of a rise in the intraluminal tubular pressure. A further decline in renal function is caused by arteriolar vasoconstriction. A prompt diagnosis is necessary to provide appropriate urological intervention. Hydronephrosis detected by renal ultrasound is an important finding. All patients with suspected obstruction should undergo bladder catheterization, as it may be therapeutic as well as diagnostic. Percutaneous nephrostomy, lithotripsy, ureteral stenting, and urethral stenting are indicated when appropriate.

DIAGNOSTIC APPROACH TO AKI

History and Physical Exam

The history and physical exam can provide invaluable clues that help determine whether the AKI is a result of a prerenal, renal, or postrenal event. A careful review of the patient's past medical history, family history, medication use, trauma, and recent febrile illnesses is essential. Furthermore, a careful assessment of fluid intake and urine output can help to narrow the differential diagnosis, as well as dictate future management. A major purpose of the physical examination in a patient with AKI is to attempt to determine the effective circulating volume. The patient's weight, blood pressure (sitting and standing), and pulse rate provide important clues. On general examination, the patient must be carefully assessed for edema, state of hydration, pallor, petechiae, rashes, and abdominal signs of tenderness, bladder fullness, and visceromegaly. Careful cardiac and pulmonary examination are performed to determine the degree of fluid overload. Clues for systemic diseases, such as rash, jaundice, arthritis, or uveitis, must always be looked for.

Urine Studies

The urinalysis, urinary sediment, and urine indices are the most important factors in determining the cause of AKI. But these must never be interpreted on their own; each value must be interpreted in relation to clinical findings and serum chemistry results. A high urine specific gravity (SG) (in the absence of proteinuria) is suggestive of decreased effective circulatory volume and prerenal AKI. An inappropriately dilute SG suggests tubular injury or interstitial nephritis. A dipstick test that is >3+ indicates intrinsic AKI with glomerular damage. Less proteinuria (<2+) may be seen in prerenal AKI, ATN, and postrenal AKI. Protein excretion of greater than 2 g/24 h suggests glomerular injury. A positive urine dipstick for blood usually indicates hematuria. However, if there are no RBCs on microscopic examination, myoglobinuria or hemoglobinuria must be considered. RBCs with RBC casts strongly suggest a glomerular lesion, especially in conjunction with significant proteinuria. WBCs and WBC casts are seen in pyelonephritis, acute postinfectious glomerulonephritis, and acute interstitial nephritis. The urinary sediment in ischemic ATN is characterized by pigmented casts, granular casts, tubule epithelial cells and casts, and cellular debris.

Urine diagnostic indices that are particularly helpful in characterizing AKI include urine sodium and creatinine concentrations. When used in conjunction with the serum sodium and creatinine, the fractional excretion of sodium (FE_{Na+}) can be calculated:

$$FE_{Na^+} = \frac{Urine_{Na} \times Plasma_{Cr} \times 100}{Plasma_{Na} \times Urine_{Cr}}$$

The results of the FE_{Na+}, urine sodium, and urine osmolality can be used to differentiate between prerenal and intrinsic AKI. A low urinary sodium (<10 mmol/L) and a low FE_{Na+} (<1%) indicate avid sodium and water retention. This is characteristic of prerenal AKI in which the intact proximal and distal tubules are able to respond appropriately to renal hypoperfusion. Conversely, the damaged tubules in ATN are unable to efficiently reabsorb sodium, and this results in a high urine sodium concentration (>10 mmol/L) and a FE_{Na+} of >2%. Two important caveats when using the FE_{Na+} to assess AKI are underlying renal disease and the concurrent use of diuretics. In postrenal obstruction, the indices are more variable and not very helpful. Early in the course, they may resemble those of prerenal AKI, but as tubular damage progresses, the indices become more similar to those of intrinsic AKI.[11,14]

Blood Studies

Evaluation of the BUN and serum creatinine concentration are essential in making a diagnosis of AKI, but the serum electrolyte concentrations more important for morbidity and mortality. The serum potassium concentration must be monitored closely in a patient with oliguria, and even more so anuria. Life-threatening hyperkalemia, particularly in association with a metabolic acidosis, must be treated immediately. Hemoglobin, hematocrit, platelet count, and serum concentrations of calcium, phosphorous, bicarbonate, and albumin must be routinely evaluated in patients with AKI. Serologic tests for *streptococcal* infection and complement studies are indicated if there are signs of AGN. It has been traditionally taught that a BUN serum–creatinine serum ratio of >20 suggests prerenal AKI, while the ratio is about 10 in ATN. Unfortunately,

this ratio is affected by many factors, including a catabolic state and gastrointestinal bleeding, that negate its value in critically ill patients.[14]

Diagnostic Imaging

The two most helpful initial imaging studies in patients with AKI are a chest radiograph and a renal ultrasonography. Chest radiographs can help define whether there is significant cardiomegaly or pulmonary edema as a result of fluid overload. Renal ultrasonography is extremely useful when either obstruction or RVT is suspected. Additionally, if it is unclear whether the patient has AKI or CKD, the ultrasound may be diagnostic. In patients with AKI, the kidneys are often large and swollen. Conversely, the kidneys in CKD are often small, scarred, or dysplastic. In both instances, they lose the normal corticomedullary differentiation and are echogenic.

Renal Biopsy

A percutaneous renal biopsy may be indicated in children with AKI if the cause is unknown or if there is any suspicion of a crescentic glomerulonephritis.

Complications of AKI

The major complications of AKI (Table 24.5) are related to either metabolic dysfunction or fluid overload. The metabolic complications of AKI are hyperkalemia, metabolic acidosis, hypocalcemia, hyperphosphatemia, hyponatremia, and rarely uremia. Hyperkalemia is the single most life-threatening complication of AKI. Hyperkalemia is the result of impaired tubular secretion, a decreased filtration fraction, and extracellular shifts of potassium induced by acidosis. Peaked T waves are usually the first manifestation of cardiotoxicity, followed by prolongation of the PR interval and widening of the QRS complex. Prompt treatment of hyperkalemia is required in order to prevent ventricular tachycardia or fibrillation. Uremia is characterized by mental status changes, evidence of serositis, and bleeding diathesis as a result of platelet dysfunction. It occurs when urea and other waste products build up in the tissues because the kidneys are unable to eliminate them adequately.

There are multiple causes for hypocalcemia in AKI, which include hyperphosphatemia, decreased gastrointestinal calcium absorption, vitamin D deficiency, and parathyroid hormone (PTH) resistance. The most important acute reason is hyperphosphatemia. The hypocalcemia is usually mild and may cause tetany if markedly reduced. The hyperphosphatemia in AKI is the result of decreased renal excretion. Metabolic acidosis is very common in AKI. Declining renal function prevents the kidneys from excreting the net acids generated by diet and normal metabolic function. Paradoxically, metabolic acidosis increases the fraction of serum calcium in the ionized form, lessening the risk of hypocalcemia. Special attention must be paid to the serum ionized calcium concentration when correcting metabolic acidosis because tetany may ensue.

Patients with oliguric or anuric AKI commonly present with hypervolemia and fluid overload. The hypertension is usually caused by fluid overload, but it may also be the result of changes in vascular tone or activation of the renin–angiotensin system. If the fluid overload worsens, the patient may develop pulmonary edema and/or congestive heart failure.

Management of AKI

There are five main principles in managing AKI:

1. Maintaining appropriate renal perfusion
2. Avoiding nephrotoxic agents
3. Establishing fluid balance
4. Maintaining electrolyte and acid–base balance
5. Providing nutritional support

In many circumstances, with the important exception of glomerular nephritides, renal hypoperfusion is a predisposing factor to the development of AKI. Optimizing intravascular volume is a fundamental principle in preventing the development and progression of AKI. If children at risk for the development of AKI are adequately hydrated prior to a known incipient insult, the extent of the renal injury can often be decreased or even prevented. This is particularly important prior to the administration of contrast media, aminoglycosides, cisplatin, or amphotericin and in preoperative patients. Adequate hydration may also prevent severe AKI in HUS in some patients. Additionally, it is important to stop or avoid medications that cause intrarenal afferent arteriole vasoconstriction (NSAIDs) or efferent arteriole vasodilation (ACEIs). Even in well-hydrated patients, potential nephrotoxic agents should only be used when necessary and with special attention to dosing schedules and by monitoring serum concentrations.

Establishing fluid balance is perhaps the most challenging and critical step in managing AKI. Prerenal AKI is the most common situation in which intrinsic renal damage can be prevented. Any hypovolemic patient who presents with oligoanuric AKI has a potential prerenal component. The first step in managing a patient with potential prerenal AKI is fluid resuscitation with one or more rapid infusions of normal saline, without any potassium, unless the patent is hypokalemic as a result of diarrhea or a tubulointerstistial disease. Maintenance fluids and replacement of ongoing losses should not be neglected during this period of initial rehydration. If the urine output does increase after the patient is assessed to be euvolemic, intrinsic renal damage must be assumed. At this stage, in the absence of increased urine output, fluid restriction becomes essential

to avoid hypertension, pulmonary edema, and congestive heart failure. During fluid restriction, the patient should receive insensible losses (400–700 mL/m^2/24 h of D5W) plus urine output losses (milliliter per milliliter replacement with 0.45% NS). If the patient becomes hypervolemic after fluid resuscitation or requires large quantities of blood products or intravenous alimentation, a diuretic, such as furosemide, is administered in an attempt to increase urine output. Diuretics must be used with caution in the absence of good evidence of euvolemia or hypervolemia because they may worsen the component of AKI. Patients who present with nonoliguric AKI (acute interstitial nephritis or the recovery phase of ATN) may actually be polyuric and require greater than normal volumes of fluid to avoid intravascular volume depletion.[15]

Maintaining the electrolyte and acid–base balance involves managing hyperkalemia, hypocalcemia, hyperphosphatemia, and metabolic acidosis. All potassium must be removed from the intravenous fluids and in any patient with oligoanuric AKI. Treatment of hyperkalemia is indicated if electrocardiogram (EKG) abnormalities are noted or if serum concentrations are higher than 6–7 mEq/L. Treatment regimens are those that protect against hyperkalemia, those that redistribute potassium intracellularly, and those that remove it from the body.[11] Calcium gluconate is cardioprotective against the conduction abnormalities induced by hyperkalemia, but it does not remove potassium. Calcium gluconate is administered (0.5–1.0 mg/kg/dose) early in the course of treatment. Redistributive measures are albuterol, bicarbonate, and insulin plus glucose infusions. All three interventions begin to shift potassium intracellularly within 30 minutes; these are only temporizing measures, and the serum potassium concentration may rise rapidly after they are discontinued. Potassium can be removed from the body via the gastrointestinal tract or the kidney, or by dialysis. Sodium polystyrene (Kayexalate) administered at 1 g/kg exchanges sodium for potassium in the gastrointestinal tract and effects potassium removal. Hypernatremia is a common side effect from excessive sodium absorption. If the patient is not anuric, loop diuretics are used to promote potassium losses by kaliuresis. Dialysis is the definitive therapy in patients who do not respond to these regimens.[11]

Hypocalcemia is usually mild and responds to correction of the hyperphosphatemia and dietary calcium supplementation with calcium. Intravenous calcium infusion is indicated if there is tetany or arrhythmia. Hyperphosphatemia is treated by dietary restriction and oral phosphate binders. Calcium carbonate and calcium acetate are well-tolerated phosphate binders when taken with meals. The treatment of the metabolic acidosis is important for maintaining a normal pH for optimal metabolism and for reducing the hyperkalemia. As previously mentioned, rapid correction of the acidosis can cause a precipitous decline in the serum concentration of ionized calcium. Oral sodium bicarbonate or sodium citrate tablets are given to correct the metabolic acidosis, but intravenous sodium bicarbonate is used for patients who have severe acidosis or who cannot take anything by mouth.

Nutritional support is essential because the patients are in a highly catabolic state. This is particularly challenging in oligoanuric patients, who may be severely fluid restricted. Formula or parenteral nutrition should be concentrated whenever possible to provide maximum calories at a minimum volume. Children typically require only modest protein restriction (1–2 g/kg/day) and maintenance (or higher if catabolic) nonprotein calories. A low-phosphorous and low-potassium diet is also required. If adequate calories cannot be maintained because of fluid restriction, dialysis should be considered early in the course.[11]

Dialysis

The indications for initiating dialysis in AKI include

1. Volume overload unresponsive to conservative management
2. Hyperkalemia, acidosis, or hyperphosphatemia unresponsive to medical therapy
3. Uremia (mental status changes, serositis, or bleeding diathesis)
4. Nutritional support

The patient's overall condition must be considered before making a decision to start dialysis. This is also important when selecting the appropriate type of dialysis. One important consideration is the patient's hemodynamic status. Hypotensive patients are poor candidates for hemodialysis but are often suitable for peritoneal dialysis or continuous renal replacement therapy (CRRT).[21] There are no precise criteria for selecting a particular dialysis modality, and practice patterns vary widely. However, CRRT is rapidly becoming the preferred modality for pediatric patients with AKI in the intensive care unit (ICU) setting.[22]

CONCLUSION

The prognosis of a child with AKI is highly dependent on the underlying cause, the length of insult, the number of other organs involved, the amount of residual urine output, and whether dialysis is required.[23] The major complications of AKI include fluid overload, hyperkalemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, and rarely uremia. Judicious management of these complications can vastly improve the morbidity and mortality associated with AKI in children. Immediate treatment of the underlying insult through fluid resuscitation in the case of prerenal injury or relieving the obstruction in postrenal injury can prevent the progression to intrinsic renal injury. Once intrinsic renal injury has been established, it is essential to maintain adequate renal perfusion while avoiding further nephrotoxic insults whenever possible. If medical management fails to control the fluid and metabolic abnormalities, dialysis may be necessary. The choice of which dialysis modality to employ primarily depends on the hemodynamic status of the patient. Recovery from intrinsic renal disease also depends on the underlying cause of the AKI. Children with acute interstitial nephritis or ATN typically recover normal renal function and are at low risk for long-term morbidity. Conversely, children who undergo a substantial nephron loss, as occurs in HUS, cortical necrosis, or RPGN, are at risk for the development of CKD long after the initial

insult. These children require lifelong monitoring of blood pressure, renal function, and urinalysis.

CHAPTER 25

Renal Transplantation

Alexander C. Small and Shumyle Alam

INTRODUCTION

Since the first human renal transplant in 1954, major advances in surgical techniques, organ donation, immunosuppression, and recipient care have dramatically improved outcomes.[1] Early transplants into pediatric patients resulted in high rates of morbidity and mortality, but in contemporary cohorts, pediatric patient and graft survival exceeds that of adults.[2] Approximately 700–800 renal transplants are performed in patients below the age of 18 in the United States each year, and currently, 989 pediatric patients are on the transplant waiting list.[3]

Although there have been many improvements in renal replacement therapy (RRT) with hemodialysis and peritoneal dialysis, renal transplant remains the gold standard treatment for patients with end-stage renal disease (ESRD). Transplant confers a significant survival advantage compared with those children who remain on the waiting list, reducing the risk of death by 75% at 2 years.[4] Children who undergo transplant also have been shown to have better growth parameters, social outcomes, and overall quality of life.[5,6] In fact, the final adult height of transplant recipients has been correlated with educational level, independent housing, paid activity, and marital life.[6] Renal transplant is cost-effective compared with chronic dialysis; however, lifetime costs remain high, on the order of $340,000 per patient.[7]

Many similarities exist between pediatric and adult transplantation, but special considerations must be made for children. There are differences in pathology leading to kidney failure, immunosuppression regimens, surgical techniques, and transition to adult care. Children also present a unique challenge due to longer life expectancy. This chapter reviews core concepts in pediatric renal transplantation, with a focus on urologic concerns among this unique group of patients.

PEDIATRIC CHRONIC KIDNEY DISEASE AND RENAL FAILURE

Chronic kidney disease (CKD) is the state of irreversible kidney damage causing a decline in renal function, substantial morbidity, and premature death. There are multiple definitions for CKD. CKD staging provided further clarification to allow an understanding of progression of disease (Table 25.1). Staging is also valuable in the follow-up of patients with congenital anomalies of the kidney and urinary tract (CAKUT) as a measure of the success of therapy. The Kidney Disease: Improving Global Outcomes (KDIGO) consortium defines CKD as any abnormalities of kidney structure or function with a glomerular filtration rate (GFR) of <60 mL/min/1.73 m^2 present for >3 months or with a GFR of >60 mL/min/1.73 m^2 with markers of kidney dysfunction (including proteinuria, albuminuria, renal tubular disorders, or pathologic abnormalities detected by history or imaging).[8] Stage 5 CKD, also called ESRD or kidney failure, refers to the state when the GFR drops below 15 mL/min/1.73 m^2. Children with ESRD have mortality rates that are 30 times higher than those without ESRD.[9] At this point, a patient must be referred for RRT or transplant evaluation.

The estimated incidence of pediatric CKD is 13.1 cases per million in the United States and 12–75 cases per million abroad.[10,11] The rate of CKD and ESRD is higher in boys due to an increased risk of CAKUT, including posterior urethral valves (PUVs), renal dysplasia, and prune belly syndrome.[12,13] Boys account for about 60% of cases of ESRD and subsequent renal transplants.

Underlying causes of CKD and ESRD originate from heterogeneous disorders that are distinct in children and adults. Whereas most cases of CKD in adults result from diabetes and hypertension, CAKUT disorders are the most common causes of CKD in pediatric patients who undergo renal transplant (Table 25.2). Overall, 45% of transplant recipients have a CAKUT diagnosis, including obstructive uropathy (21%), renal dysplasia or aplasia (18%), reflux nephropathy (8%), and polycystic kidney disease (4%). Patients with CAKUT can be affected with just one of these conditions, but they are more commonly found to have multiple issues along a spectrum. The remainder

TABLE 25.1 Chronic kidney disease stages

Stage	Estimated GFR (mL/min/1.73 m^2)	Prognosis
1	≥90	Normal GFR
2	60–89	
3A	45–59	Low risk of progression
3B	30–44	Intermediate risk of progression
4	15–29	High risk of progression and complications
5	<15	Kidney failure

Abbreviation: GFR, glomerular filtration rate.

[a] Indicates diagnoses that may be present outside of the CAKUT spectrum.

of CKD cases result from glomerular diseases, like focal segmental glomerulosclerosis (11.5%), and acquired conditions, like hemolytic uremic syndrome (2.6%), renal infarct (1.3%), or Wilms' tumor (0.5%).[12] In one study, cases that progressed to ESRD occurred in 41% of patients with glomerular diseases and 29% with nonglomerular diseases.[14] Predictors of faster CKD progression were proteinuria, hypoalbuminemia, hypertension, dyslipidemia, and anemia.

Ultimately, a third of children with CKD who require RRT will be found to have a urologic abnormality, and 39% of children on the transplant waiting list carry a CAKUT diagnosis.[15] However, these disease processes are heterogenous, and primary diagnoses listed in reports may not provide enough information for precision in understanding the course of disease. There is potential for confusion and misclassification with the current system. For example, a patient diagnosed as "obstructive uropathy" may also have "aplasia, dysplasia, or hypoplasia" of the kidney. These categories, which are almost equally weighted, account for 30% of the pediatric patients undergoing transplant in the United States. Pre- and posttransplant course can vary dramatically depending on whether the dysplasia was related to obstructive uropathy. An attempt to decrease some of this confusion, including garnering a true understanding of the urologic causes of renal disease in children, may lie with the diagnosis of CAKUT. This broad term encompasses the majority of renal diseases involving the urinary tract and may allow us to better understand the ultimate course of the pediatric urologic patient with progressive CKD. Data from other countries that report suggest that patients with CAKUT comprise between 36% and 58% of patients with progressive CKD. The pediatric urologist has a pivotal role in the workup and management of a majority of these patients and may play a large role in the management after transplant.

PRETRANSPLANT EVALUATION

Medical Evaluation

Medical evaluation of children before renal transplantation is generally undertaken by a multidisciplinary team involving nephrologists, pediatric urologists, transplant surgeons, and other specialists as needed (psychiatrists, cardiologists, pulmonary or critical care physicians, etc.). There are several major requirements for the evaluation and preparation for renal transplant that have been shown to improve long-term outcomes and reduce complications.[2]

First, any contraindications to transplantation must be ruled out (Table 25.3). Absolute contraindications include active malignancy, systemic sepsis, multiorgan system failure, and irreversible extrarenal disease. Ongoing substance abuse and anticipated noncompliance are also contraindications that may be modifiable through work with a psychiatrist or social worker. Any active infections must be fully treated before immunosuppression can begin.

Next, human leukocyte antigen (HLA) matching must be performed, and any anti-HLA antibodies to the potential donor must be detected. Identical twin or sibling donors will have the best HLA match, but many pediatric patients will not have brothers or sisters available for organ donation. Therefore, most live donor allografts come from parents who will have a single haplotype match. This has implications for immunosuppression and tolerance induction.

TABLE 25.3 Contraindications to transplantation

Absolute contraindications
Malignancy (within 2 years)
Systemic sepsis
Multisystem organ failure
Severe untreated extrarenal disease (cardiopulmonary, neurologic, psychiatric, etc.)
Antiglomerular basement membrane antibodies (Goodpasture's disease)
Active substance abuse
Relative contraindications
Noncompliance
Lack of adequate social support
Severe malnutrition
Ongoing active infection
Rapidly progressive disease (i.e., hemolytic uremic syndrome)

The cardiovascular and nutritional status of patients is also important before transplantation. Many pediatric patients with ESRD are underweight and need aggressive nutritional support. Likewise, CAKUT patients can have urine-concentrating defects and fixed-urine outputs leading to large-volume fluid losses. Gastrointestinal access with a gastrostomy tube may be required for certain patients to achieve adequate nutritional intake, fluid balance, or medication administration.[16] Phosphate binders, vitamin D supplementation, and serum thyroid monitoring have been shown to prevent posttransplant bone disease.[17] On the other hand, weight control and prevention of obesity can reduce surgical and anesthetic risks, and mitigate weight gain after transplant.[18]

Routine immunizations must be completed prior to undergoing transplant. Vaccines protect from infectious diseases of childhood, but they may not be effective if administered to an immunocompromised patient. Antibody titer monitoring and booster doses may be required due to decreased immune responses in patients with ESRD.[2] Furthermore, live vaccines (especially varicella and measles) should be avoided in the setting of immunosuppression.[19] The influenza vaccine should be administered annually starting 6–12 months after transplant.

Hematologic evaluation includes a risk assessment of the transplant recipient for thrombotic complications. Vascular thrombosis accounts for 9.8% of graft losses.[12] Studies have identified several risk factors, including age of less than 2 years, hypercoagulable states like factor V Leiden or antiphospholipid antibodies, prior large-vein thrombosis, dialysis access thrombosis, and longer graft cold ischemia time.[20] If properly identified, patients with increased risk can be managed with anticoagulation prophylaxis and have outcomes comparable to those without risk factors.[21]

Finally, psychological and social issues must be considered. A systematic review found that 32% of patients had some degree of nonadherence to immunosuppressive regimens after kidney transplant, and 44% of graft losses were associated with nonadherence.[22] Most factors associated with nonadherence were socioeconomic (including lower income and lack of family support), psychological (including depressive symptoms or anxiety), and knowledge related (including confusion over regimens or poor communication with medical team). Preoperative education, counseling, and planning for strict follow-up protocols are required to ensure compliance and stability after transplant.[23] Social work involvement is also needed to ensure adequate insurance coverage is in place.

Urological Considerations

The high prevalence of urologic pathology in children with CKD and ESRD demands early urological evaluation and treatment. Abnormal urinary tract function can have a deleterious effect on kidney function, and intervention may be able to delay the need for transplantation. The goals of any pediatric urologist as part of a multidisciplinary team with nephrologists and transplant surgeons should be to optimize the bladder or appropriately reconstruct it prior to transplant and consider appropriate management of the native kidneys.[24] Workup generally involves serum chemistries, GFR estimation (with creatinine or cystatin C), functional urodynamic studies, cystoscopy to characterize any structural abnormalities, and renal ultrasound.

Currently, there are no guidelines for the best management of patients with CAKUT and progressive CKD. Limited data on progression and posttransplant outcomes are available, with few reported series directly comparing CAKUT outcomes with other causes of progressive CKD. There may be an opportunity for standardization and better assessment of pre- and posttransplant course when reviewing the CAKUT patients as a group. Pretransplant evaluation and management is not standardized, but many centers are employing a multidisciplinary approach to CAKUT patients. Identification of bladder dysfunction, upper tract anatomic abnormalities, urethral abnormalities, and vesicoureteral reflux (VUR) is important for successful long-term graft survival (Figure 25.1). The follow-up and treatment of these conditions, once identified, is variable.

Patients with neurogenic bladder dysfunction can have very high voiding pressures, abnormal storage volumes, and incomplete bladder emptying. Pressures of more than 40 cm of H_2O have been shown to have damaging effects on renal function through increased papillary pressure and intrarenal urine reflux.[25] Detrusor sphincter dyssynergia, secondary VUR, hydronephrosis, and chronic urinary tract infections (UTIs) all contribute to upper tract deterioration. Early workup with urodynamic studies focusing on compliance, leak point pressure, voiding pressures, and residual volumes, followed by aggressive bladder management with anticholinergics plus clean intermittent self-catheterization (CIC) and/or augmentation cystoplasty, can mitigate some of this potential damage.

Likewise, patients born with PUV can have lifelong bladder dysfunction, termed valve bladder, and a quarter will progress to ESRD.[26,27] Younger children exhibit high voiding pressures and low bladder compliance, which often necessitates a urinary diversion with a vesicostomy early in life or high-dose anticholinergic therapy with CIC.[28] Historically, undiversion was thought to be necessary

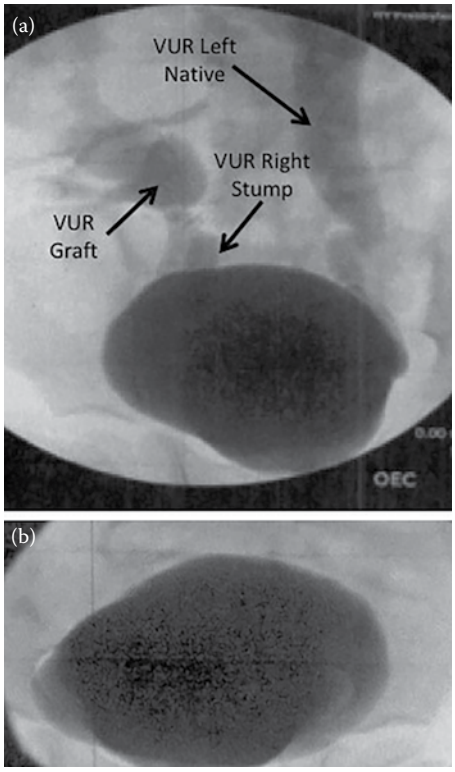

FIGURE 25.1 VUR after renal transplant. (a) Voiding cystourethrogram from a patient with three refluxing units after renal transplant. The patient had no urologic interventions performed before transplant, and the posttransplant course was complicated by delayed graft function and urosepsis. He underwent ureteroureterostomy to join the transplant ureter to the ureteral stump with simultaneous bilateral ureteral reimplantation of the native ureteral stump and left ureter. (b) Postoperative voiding cystourethrogram from the same patient with reflux is resolved.

prior to transplantation to evaluate bladder function and determine if there is a need for augmentation.[29] However, recent series have demonstrated the safety of transplanting a kidney into a diverted system.[30] Over time, severe polyuria and dysfunctional voiding can cause chronic bladder overdistension. Older children exhibit low voiding pressures and large bladder capacities, so efforts including timed voiding, CIC, and/or overnight catheterization should focus on maintaining a low postvoid residual volume to prevent urinary stasis and infections.[31] Pediatric urologists are critical to the care of these patients before, during, and after their transplants.

Risks and benefits should be weighed prior to performing an augmentation cystoplasty. The relationship between high intravesical pressures and transplant graft deterioration is well established, so augmentation is sometimes necessary to guarantee a low-pressure reservoir.[32,33] In several small case series, graft survival seems to be equivalent in patients with augmented bladders and those who have normal bladders.[34–36] Ileocystoplasty is the most common method of bladder augmentation, but risks include mucus production, bladder lithiasis, difficulty emptying, and metabolic acidosis. Alternatively, gastrocystoplasty can obviate some of these problems, but has different disadvantages, including hematuria or dysuria syndrome and rare alkalosis. The risk of malignancy is a concern for some, but is estimated to occur in <5% of cases.[37] Regardless, surveillance with cystoscopy and ultrasound is recommended beginning 10 years after augmentation.[38] Autoaugmentation and ureterocystoplasty were performed historically, but both techniques have fallen out of favor.[39] Augmentation can be performed either when the patient is ready for transplant listing or 6–12 weeks before a scheduled living donor transplant, prior to starting immunosuppression. For patients on peritoneal dialysis, it is important to realize that any transperitoneal surgery can compromise this approach by creating serosal disruptions and adhesions that will interfere with ultrafiltration. To avoid these adverse consequences altogether some urologists forgo augmentation of small-capacity bladders and have shown satisfactory outcomes with transplantation.[40]

The management of retained native renal units can also be a concern for urologists. Residual excretory capacity and erythropoietin production can provide physiologic benefit; however, issues like reflux and infection can present challenges.[41] Conflicting studies have suggested an increased incidence of UTI in patients with VUR.[42,43] The management of VUR in this setting is controversial, with options including observation, endoscopic bulking injection, ureteral reimplantation, and native nephrectomy. One study showed no difference in infection rate between observation and native nephrectomy, but decreased infections with reimplantation.[44] For high-grade reflux, reimplantation is preferred because it maintains the native ureters in case they are needed for future complication management with ureteroureterostomy or ureteropyelostomy.

Native nephrectomy is indicated for patients with persistent high-grade reflux, chronic renal infections (i.e., xanthogranulomatous pyelonephritis), infected renal stones, cystic disease, or refractory hypertension. Heavy proteinuria (>40 mg/m^2/h) can also merit native nephrectomy to eliminate protein loss and potentially decrease risk of thrombotic events.[41,45,46] Nephrectomy can be performed early, several weeks before transplant or simultaneously with transplant. However, some conditions, like xanthogranulomatous pyelonephritis or polycystic kidney disease, may make nephrectomy at the time of transplant too difficult or risky. When performing a nephrectomy before transplant, it should be approached from a flank or dorsal lumbotomy incision to account for the future transplant incision. For patients on peritoneal dialysis, a retroperioneal minimally invasive approach has been shown to preserve peritoneal integrity.[47] Finally, nephrectomy may reduce the risk of graft hypoperfusion by reducing organ steal and volume depletion from large native urine output.[41] The decision to perform native nephrectomy should be individualized with a discussion of potential risks and benefits of this strategy.

RENAL TRANSPLANTATION

When a patient becomes designated as stage 4 CKD with a GFR of <30 mL/min/1.73 m^2, it is time to start discussing potential RRT and possible renal transplantation.[48] The timing of deceased donor renal transplant (DDRT)

can be unpredictable. Living donor renal transplant (LRT) is more common in pediatric patients and confers certain advantages.

Deceased Donor

After revision of the kidney allocation policies in 2005 to prioritize organs from deceased donors of <35 years old to pediatric patients, the mean wait time decreased to 165 days or less from 360 days. Further changes to the Organ Procurement and Transplant Network (OPTN) kidney waiting list were put into effect in 2014, which now assigns points for pediatric patients, time on the wait list, sensitization, and quality of HLA match.[49,50] Currently, there are large geographic variations in waiting times for pediatric DDRT, which are associated with local organ donor supply and demand factors.[51] In 2015, 76% of all donor kidneys in the United States were from deceased donors.[15]

Organ donation from brain-dead individuals is coordinated by professionals on a local level, where evaluation, consent, and medical management are performed in a structured approach.[52] Organ retrieval is performed through a complete midline incision. After the aorta is flushed with cold preservation solution and the abdomen is packed with sterile saline ice slush, organs are sequentially removed, starting with the heart and ending with the kidneys. Kidneys are removed en bloc with adjacent aorta, vena cava, and ureters, which are divided at the bladder. They are then separated and prepared for transfer to their final destination.

While LRT is generally preferred over DDRT due to improved graft survival, deceased donor organs are preferred in certain cases where there is high risk for disease recurrence. For children with focal segmental glomerulosclerosis, 5-year allograft survival was comparable (60%–70%) for deceased donor and living donor organs.[53] In general, the best kidney for a child is one from a healthy teenager or young adult. Adult kidneys can be transplanted into children once they are more than 6.5 kg. Graft survival is low for deceased donors of less than 2 years old (51% 5-year survival) or more than 50 years old (58% 5-year survival).

Living Donor

Allografts from living donors have a significantly lower incidence of delayed graft function and better long-term graft survival than DDRT.[15] The failure rate at 5 years for LRT is 11.1% compared with 18% for DDRT. Notably, this advantage is lost when living donors are older than 55.[54] LRT allows for the planning of preemptive transplantation before the initiation of dialysis. Preemptive transplantation occurs in 25% of pediatric patients, as parents often try to avoid dialysis for their children.[12] This strategy has multiple advantages, including decreased cost, improved quality of life, prolonged graft survival, and improved overall survival.[55–58] One hypothesis was the ability to start immunosuppression early, but a randomized trial in 2003 showed that starting immunosuppression with cyclosporine and azathioprine before kidney transplant had no advantage over starting immunosuppression after.[59] Avoiding morbidity of vascular access and dialysis complications contributes substantial benefit.[58] Contraindications for preemptive transplant are active autoimmune disease, ongoing infection, need for transplant nephrectomy, and noncompliance.

Urologists are often involved in the workup and care of live kidney donors. Donors require a thorough history and physical exam, a psychiatric evaluation, and laboratory testing with blood typing, renal assessment, infectious screening, and malignancy screening. Donors must be reevaluated every 6–12 months to ensure continued medical and psychosocial suitability.[60] Since donation to a family member or altruistic donation can be fraught with emotions, informed consent with meticulous discussion of the risks of donation is critical. The most common postoperative complications are hematoma and abscess. The most serious long-term consequence for kidney donors is a 3.5–5.3 times elevated risk of developing ESRD, with even more risk for those with lower GFR, albuminuria, hypertension, current or former smoking, diabetes, and obesity.[61]

Living donor nephrectomy is often performed simultaneously with the exposure of the recipient. Alternatively, successful paired-exchange programs have been set up to increase access to living donors by facilitating simultaneous and nonsimultaneous organ swaps.[62,63] For the last 20 years, donor nephrectomy has been performed laparoscopically.[64] During the operation, particular care must be taken to preserve ureteral length by dissecting to the level of the bladder and to maintain blood supply, avoiding ureteral skeletonization. After the renal vessels are ligated, the kidney is extracted and flushed immediately with cold preservation solution. It is then placed in sterile saline ice slush and delivered to the recipient.

Close follow-up for the living donor is required due to these long-term risks. Some have advocated donor registries where these patients can be tracked. In cases where donors lose their remaining kidney due to trauma, cancer, or medical renal disease, they are given a very high priority on the OPTN kidney waiting list.[65]

Recipient Management

Children should be optimized immediately before transplantation. First, those with ESRD should undergo dialysis on the day of the transplant. Maintenance of appropriate volume status facilitates perfusion of the new graft.[66] Second, in multiple modern adult cohorts, immune induction therapy with antibodies targeting T cells (i.e., thymoglobulin, alemtuzumab, basiliximab, etc.) has been shown to decrease rates of acute rejection by one-third.[67] Despite mixed data in the pediatric literature, induction therapy is now routine practice in many pediatric patients, and specific protocols vary by medical center. Otherwise, patients require routine surgical preparation, including nothing to eat, vascular access, anesthesia consultation, and administration of prophylactic antibiotics.

For children more than 20 kg in weight, the pediatric renal transplant procedure is identical to that in adults—retroperitoneal exposure is achieved through an anterior, lower-quadrant "hockey stick" incision. Venous and arterial anastomotic sites along the common or external iliac artery and vein are identified. Overlying lymphatics

are divided between ligatures or clips to decrease the risk of postoperative lymphocele. After vascular control is achieved, venotomy and arteriotomy are made and venous and arterial anastomoses are sewn in place. Reconstruction of the renal vessels through spatulation, reanastamosis, and/or caval or aortic patches may be required due to variations in vascular anatomy. For young children less than 20 kg, a transabdominal approach can be utilized through a midline incision, and the kidney can be placed intraperitoneally with anastomoses to the aorta and vena cava.[2] In certain small children or when a small donor kidney is used, an extraperitoneal approach can be attempted, but it often requires closure of only the external layers, with delayed hernia repair. The new graft will immediately sequester 250–300 mL of blood, so maintenance of adequate blood pressures is essential to prevent posttransplant hypotension.[66]

Ureteral reimplantation can be performed directly into a native bladder (ureteroneocystotomy) using a transvesical "Leadbetter–Politano" technique or extravesical "Lich–Gregoir" technique. In a meta-analysis of two randomized trials and 24 observational studies, the extravesical Lich–Gregoir technique was favored due to reduced rates of anastomotic leakage and postoperative hematuria. Rates of ureteral stricture and incidence of VUR did not differ between techniques.[68] The Lich–Gregoir ureteral reimplantation also causes less discomfort and fewer bladder spasms.[69] Prophylactic stenting of the ureterovesical anastomosis is protective from major urologic complications (relative risk 0.24), including urine leak and obstruction.[70] The disadvantages of stent placement are an increased rate of UTI if the stent is left in place for more than 30 days and increased costs.[71] Some centers perform ureteroneocystotomy without stent placement unless there is an increased risk of urinary retention or high pressure.[72] Ureteroureteral anastomosis is an alternative reconstruction option in the setting of a small hypertrophied bladder, a very short transplant ureter, or a salvage procedure. A retrospective series of 23 patients showed acceptable outcomes with an 8% leak rate and no graft failures.[73] Regardless of approach, a Foley catheter is left in place postoperatively for 2–5 days.

POSTOPERATIVE CARE

Immediate postoperative care of transplant recipients can be complex and require coordination between multiple specialists. Daily clinical exam and monitoring of urine output, vital signs, and laboratories must be conducted. Special considerations are made for functional monitoring of the allograft, cardiovascular and respiratory support, fluid and electrolyte management, immunosuppression, and infection prophylaxis.

Monitoring fluid and electrolyte status is critical in the first days following surgery since hypotension can contribute to early graft loss. It is important to consider insensible losses from surgery and high urine output from a new kidney that cannot yet concentrate urine. Conversely, hypertension may occur in up to 80% of transplant recipients in the setting of fluid overload, steroid or calcineurin inhibitor treatment, donor factors, or renal artery stenosis. In the long term, elevated blood pressures can result in graft dysfunction, left ventricular hypertrophy, and death.[74] Calcium channel blockers are safe and effective for first-line therapy in the acute setting after surgery.

Pediatric immunosuppression regimens have rapidly evolved over the last 20 years with the introduction of induction antibodies that can downregulate immune response and the improved understanding of maintenance therapies. Immunosuppression is highest during the first 3–6 months after transplant, when the risk of acute rejection is highest, and then it is slowly tapered to maintenance levels. Ideally, adequate therapy is achieved while minimizing adverse effects, such as infection, nephrotoxicity, and malignancy. Outcomes of clinical trials and current protocols have been reviewed recently in the literature.[2,75]

Prophylaxis against infection is recommended in the initial months following transplant since infection is the leading cause of hospitalization and death after transplant.[76] UTI is the most common infection, occurring in 27%, and children with abnormal lower urinary tracts have increased risk.[77] Fortunately, UTI seems to have no effect on graft survival for patients on prophylactic antibiotics.[78] Antibiotic coverage with daily trimethoprim-sulfamethoxazole can prevent UTI and *Pneumocystis jirovecii* pneumonia. These children may benefit from lifelong antibiotic prophylaxis.

Infection with opportunistic viruses like cytomegalovirus, BK virus, Epstein–Barr virus (EBV), herpes simplex virus, and human immunodeficiency virus can cause graft dysfunction, complications, and even death. Prophylaxis from CMV with valganciclovir or ganciclovir significantly reduces infection and associated complications.[79] Screening and treatment of other opportunistic viruses with antiviral agents and modified immunosuppression regimens is detailed in the KDIGO clinical practice guideline for the care of kidney transplant recipients.[80]

COMPLICATIONS

Early Graft Dysfunction

Delayed allograft function is defined by the need for dialysis during the first week after transplant. Causes include acute ischemic injury, vascular thrombosis, surgical and urologic complications, and hyperacute rejection.[81] Delayed graft function occurs more frequently in DDRT (19%) than LRT (6%), and results in a six times greater risk of graft failure. Hyperacute rejection occurs within the first minutes of transplantation and is mediated by anti-HLA antibodies that activate the complement cascade against the allograft.[82] Acute rejection occurs in the days to months after transplantation and is defined by an acute deterioration in allograft function. Classic signs of acute rejection are fever and graft tenderness, but with modern immunosuppression, these signs are rarely found. Acute rejection is detected with a rise in serum creatinine and must be confirmed with graft biopsy. The rates of acute rejection are dropping—whereas rates in the late 1980s were 53% and 67% for LRT and DDRT, they are now 9% and 14%, respectively.[12] Although complete recovery from an acute rejection episode is possible, the likelihood

decreases with each subsequent episode. Patients with acute rejection have triple the risk of developing chronic rejection and loss of allograft over time.[83] Research is ongoing for new biomarkers to detect acute rejection earlier.[2]

Surgical Complications

Surgical and vascular complications are a major cause of graft loss. Wound complications are rare, but they can be devastating. Infection occurs in 2%–7% of cases.[84] Surgical site hemorrhage has been seen in 1%–5% of cases, and can result in significant blood loss, hematoma, and graft dysfunction or loss.[85] Spontaneous allograft rupture is a dangerous complication of transplantation, and occurs in 0.3%–3% of cases. Risk factors are acute rejection, acute tubular necrosis, and renal vein thrombosis, and salvage rates vary from 30% to 50%.[86]

Renovascular complications, including renal artery stenosis and vascular thrombosis, happen in 15% of cases.[87] Renal artery or vein thrombosis usually occurs within the first 3–5 days of transplant, and is the third most common cause of graft loss. Causes can be either technical (anastomotic defect or external compression) or nontechnical (young donor or recipient, low arterial flow, intimal injury, or hypercoagulability). Prevention of thrombosis through preoperative hematologic screening, anticoagulation prophylaxis, and hemodynamic monitoring was previously discussed.[21] Renovascular complications often require surgical revision, which can be performed with percutaneous angioplasty or primary repair.[88]

Urological Complications

Acute urological complications occur in 5%–22% of pediatric transplants.[72,87] Postoperative urinary obstruction and urine extravasation are the most common complications. Extravasation results from anastomotic leak, ureteral necrosis, or bladder injury, and is managed conservatively with stenting and bladder drainage or surgically with nephrostomy drainage, dilation, or reimplantation. Case series have shown that urological complications are not associated with donor type, preexisting urological pathology, surgical technique, or patient age.[72] Ureteral obstruction is more common in boys with PUV, but can also result from transient ureteral edema, anastomotic stricture, or hematuria with clots. In one case series, half of the patients with ureteral obstruction presented within 100 days of transplant, and 79% were found to have obstruction at the level of the ureterovesical junction.[89]

Urolithiasis can also affect transplant recipients. Stones are formed in 6% of adults and 1% of pediatric patients after transplant.[90] Diagnosis and treatment can be challenging since obstruction will not cause typical renal colic, and endoscopic access to a transplant kidney can be problematic. In the largest series of 20 patients, the presenting signs and symptoms were UTI (40%), hematuria (35%), dysuria or straining (45%), and asymptomatic (10%).[91] Risk factors identified included retained suture material, hypercalciuria, recurrent UTI, and urinary stasis. Other factors that contribute to stone formation in transplant patients are low urine output, alkaline urinary pH, hypomagnesuria, hypocitraturia, and hyperparathyroidism.[92] Stones can be treated with extracorporeal shock wave lithotripsy, retrograde ureteroscopy, or percutaneous nephrolithotomy, but comparative effectiveness data between these techniques are scant.

Postoperative VUR is noted in up to 58% of transplants.[93] If incidentally detected during screening or urodynamics, there appears to be no effect on graft survival.[72,94] However, if hydronephrosis and/or pyelonephritis develops, outcomes are worse.[95,96] Urologic disorders that predispose patients to transplant VUR include noncompliant bladder, detrusor overactivity, PUVs, or urethral stricture.[97] In certain cases with incompletely controlled bladder dysfunction, aggressive bladder management with anticholinergic pharmacotherapy and CIC can be enough to decrease urinary stasis and prevent renal damage. Endoscopic management with injection of collagen bulking agents has been attempted in transplanted kidneys with limited success.[98,99] Ureteral reimplant and/or submucosal tunnel lengthening has been shown to have success rates of almost 100%.[97] This procedure is performed in a small fraction (2%) of pediatric transplant recipients nationally.[100]

LONG-TERM FOLLOW-UP

After pediatric transplantation, the goal is to maintain allograft function and facilitate normal growth and development. Graft survival has dramatically increased with improved pretransplant preparation, better donor selection and matching, new immunosuppressive regimens, and posttransplant care pathways. One study of national trends in kidney transplant outcomes showed that each year since 1987 has conferred a 5% decreased hazard of graft loss, delayed graft function, and death.[101] Allograft survival is now 97% at 1 year, 78%–86% at 5 years, and 60%–78% at 10 years.[12] Long-term survival for children has consequently improved due to increased graft survival and decreased morbidity from surgery. According to the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) 2014 annual report, patient survival estimates for all patients at 1, 2, 5, 7, and 10 years posttransplant were 97.9%, 97.1%, 94.9%, 92.8%, and 89.9%, respectively.[12] Posttransplant survival is lowest in infants of <24 months old who receive deceased donor grafts, and they have a 3-year survival of 93.4%. LRT was associated with better survival (hazard ratio 0.79), whereas graft failure requiring dialysis was associated with much higher mortality (hazard ratio 4.85).[102] Those who lose a transplant graft must then compete with first-time candidates for subsequent DDRT and have higher rates of sensitization.[9] Some predict that modern transplants may last as long as 35 years, but these data have yet to mature.

The main causes of death in adults who have undergone renal transplantation are cardiopulmonary disease (15%) and infection (28%). Hypertension is common in up to 80% of recipients and is associated with chronic graft injury, decreased graft survival, cardiovascular complications, and mortality.[103] Furthermore, the rates of metabolic syndrome, diabetes, and left ventricular

hypertrophy all significantly rise after transplant.[104] Late graft failure usually results from chronic graft injury, calcineurin inhibitor nephrotoxicity, atherosclerosis, and recurrent renal disease (Table 25.4). Malignancy also contributes a substantial cause of death (11%). Immunosuppression is associated with development of malignancy. The overall malignancy incidence is 2.6%, with 84% developing lymphoproliferative disorders and 16% developing other cancers.[12] EBV-driven posttransplant lymphoproliferative disorder is the most common malignancy after transplant, and its prevalence has increased since the 1980s. Fortunately, due to earlier diagnosis and better therapies, survival has improved to 87% at 5 years from 48% in the 1990s.[105] Solid tumor risk is 6.7 times greater in pediatric transplant recipients than in the general population, and the most common tumor type is renal cell carcinoma.[106] As pediatric patients age, screening for preventable causes of death will become increasingly important.

Adolescents have been identified to be at very high risk during the transition period from pediatric to adult care due to high rates of nonadherence. As patients move toward increased autonomy and independence, issues arise, including missed clinic appointments, skipped tests, and medication noncompliance.[107] Rates are estimated between 5% and 50%, and nonadherence has been shown to be an important contributing factor for graft failure in teenagers.[22] Factors associated with poor adherence include older patient age, family stress or low family cohesion, patient psychiatric issues (distress, depression, or poor behavioral functioning), and poor patient knowledge. These findings underscore the need for new approaches, such as transition skills workshops and smartphone checklists to enhance compliance during this stage.[108]

TABLE 25.4 Causes of graft loss

Cause	N	%
Total	**3045**	**100**
Rejection	**1545**	**50.7**
Chronic rejection	1089	35.8
Acute rejection	396	13.0
Accelerated acute rejection	41	1.3
Hyperacute rejection	19	0.6

CONCLUSIONS AND FUTURE DIRECTIONS

Over the last 30 years, major advances in pediatric renal transplantation have been achieved. Improved understanding of pediatric renal pathology, the developing immune system, and surgical techniques has contributed to greatly improved graft and patient survival in the modern era. In the future, improved understanding of the genetics, developmental biology, and natural history of CAKUT disorders will contribute to improved treatment. Advances in immune modulation with tolerance induction have the potential to revolutionize organ transplantation and improve the quality of life for patients after surgery. Urologists have become critical members of the multidisciplinary care involved in the pretransplant, intraoperative, and posttransplant care of these pediatric patients. Evaluation and management of any urinary tract dysfunction is essential for the success of transplantation.

CHAPTER 26

Renal Calculus Disease

Pramod P. Reddy and Eugene Minevich

INTRODUCTION

The purpose of this chapter is to review the current knowledge of pediatric urolithiasis, with the emphasis being on the pathophysiology, clinical presentation, evaluation, and medical management of this condition. The surgical management of urinary calculi will be addressed in a separate chapter.

It is well established that pediatric urolithiasis is a distinctly different condition and is not as common as adult urolithiasis; however, there are quite a few similarities in the presentation and evaluation of this condition regardless of the age of the patient. Pediatric urolithiasis can be either a sporadic occurrence or an important manifestation of certain disease conditions with lifelong implications.

EPIDEMIOLOGY OF PEDIATRIC UROLITHIASIS

Children account for only 2%–3% of all patients with calculous disease.[1,2] Pediatric urolithiasis is endemic to certain developing countries and until recently was a relatively rare condition in the western hemisphere. *The incidence in the United States has been increasing over the past decade, possibly due to changing dietary and physical activity patterns in our pediatric population.*[3,4] There has also been a shift in the pathophysiology of the stones encountered in the United States. Previously, the majority of the stones were felt to be secondary to an identifiable underlying metabolic disorder.[5,6] Recent data, however, suggest that pediatric urolithiasis is evolving to a more adult-type pathophysiology, most likely due to changing dietary habits, increased incidence of childhood obesity, and lack of regular exercise in this age group.

Urinary calculus disease is more common in Caucasians, less commonly affecting those of African or Latin American heritage.[1] Boys and girls appear to be affected equally, despite earlier data suggesting a male preponderance.

The mean age at presentation is 6.9 years for girls and 5.2 years for boys.[7] Infected stones tend to occur more frequently in children under 4 years of age. *In the pediatric population, the rate of recurrence of stones is as high as 40%–70%*[8,9] and appears to be the highest for children with underlying metabolic risk factors.[8,10] *It is the high recurrence rate that prompts us to suggest that all children with stones undergo a metabolic evaluation.*

CLASSIFICATION

Several classification systems have been proposed to organize pediatric stone disease. The schema proposed by Smith is one of the most comprehensive and useful systems that we have encountered (Table 26.1).[88]

PATHOPHYSIOLOGY OF UROLITHIASIS

Formation of a stone in the urinary tract is a consequence of complex physical processes and represents the end manifestation of a multitude of diseases. The stone is produced as the culmination of many interrelated anatomic and physiochemical processes.[11] The major factors are supersaturation of lithogenic ions and crystallization of compounds in the urine (Figures 26.1 and 26.2). The formation of stones is influenced by urinary volume, pH, and the presence of urinary ions or compounds that function as promoters or inhibitors of lithogenesis (Figure 26.3).

The central event in calculus formation is supersaturation. If a urinary solute exceeds its solubility product (K_{sp} = a constant that is equal to the product of the concentrations of the pure chemical components at which the solid and the dissolved states are in equilibrium in water at standard conditions and temperature), crystallization of the solutes can occur. In normal individuals, urine is undersaturated. When a solute is added to a solvent, it dissolves in it until an equilibrium point is achieved (SS = 1). Beyond this point (i.e., between saturated and supersaturated states—*metastable zone*), no further dissolution is possible, but new nuclei do not form spontaneously.[12]

In normal urine, the concentration of a component necessary to reach supersaturation is several times higher than would be expected from its solubility because of the presence of naturally occurring organic and inorganic inhibitors that raise the K_{sp} of the urinary solutes (i.e., magnesium, citrate, pyrophosphate, glycosaminoglycans, nephrocalcin, and the Tamm–Horsfall protein).[13–17] Complexing agents are substances that form soluble complexes with specific crystals. Depending on the specific stone-forming substance, some chemicals, such as citrate and magnesium, may act as a complexor and/or an inhibitor.

Once urinary solutes exceed their K_{sp}, the solvent is said to be saturated (*unstable zone*) (Figure 26.1). Crystallization occurs via homogenous nucleation (on itself) or heterogeneous nucleation (on top of particulate matter, i.e., other crystals, cells, and tubular casts).

TABLE 26.1 Classification of urolithiasis in children

Enzyme disorders
• Primary hyperoxaluria (enzyme deficiency of)
• Type 1: Glycolic aciduria
• Type 2: Glyceric aciduria
• Xanthinuria (enzyme deficiency of)
• 1,8-Dihydroxyadeniuria
• Lesch–Nyhan syndrome (hyperuricosuria)
• Phosphoribosylpyrophosphate synthetase superactivity
• Orotic aciduria (enzyme deficiency of)
Renal tubular syndromes
• Cystinuria
• Renal tubular acidosis (Types 1–4)
Hypercalcemic states
• Hyperparathyroidism
• Immobilization
Uric acid lithiasis
Enteric urolithiasis
Idiopathic calcium oxalate urolithiasis
• Solute excess
• Hypercalciuria
• Absorptive
• Renal
• Hyperoxaluria
• Hyperuricosuria
• Medications excreted into the urine (sulfadiazine, indinvir, etc.)
Endemic bladder stone formation
Secondary urolithiasis
• Infection
• Obstruction
• Structural abnormalities
• Urinary diversion procedures
• Foreign body (ureteral stent, suture, etc.)

Source: Modified from Smith L, Segura J. *Urolithiasis*. Philadelphia: WB Saunders 1990:1327–52.

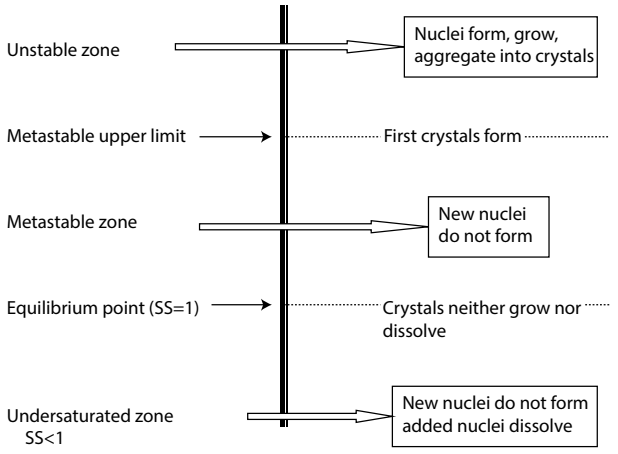

FIGURE 26.1 Urine is a complex solution and contains inhibitors and complexing agents that interact with other constituents, allowing a higher concentration of ingredients. After reaching a metastable upper limit, the solvent is said to be saturated (*unstable zone*) with the salt, and if more salt is added, if temperature and pH are unchanged, it crystallizes in the solution.

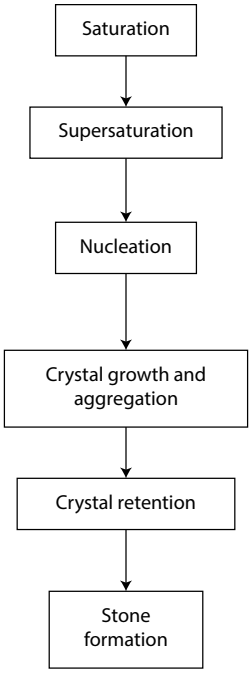

FIGURE 26.2 In urine, nuclei usually form through heterogeneous nucleation. Cells and other crystals can act as nucleating foci. Urine does not need to be continuously supersaturated for crystals to grow. If nuclei come in close contact and bind to each other (due to chemical and/or electrical forces), crystal aggregation starts.

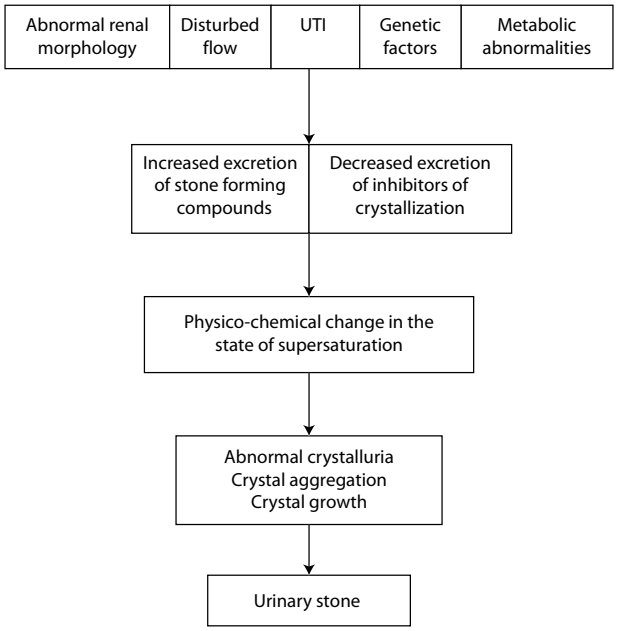

FIGURE 26.3 Renal, urologic, endocrine, and metabolic disorders may lead to the development of crystallized material in the urinary system. Abnormal renal morphology, disturbed urinary flow (obstruction, VUR, and neurogenic bladder), UTIs, systemic metabolic abnormalities, and predisposing genetic factors may all play a role in the increasing excretion of stone-forming constituents, crystal aggregation, and retention. The same factors may cause a decrease in excretion of inhibitors or complexing agents of crystallization.

In vivo, heterogeneous nucleation is much more common. Once this process is initiated, growth of the stone is fostered by the nuclei coming in close contact and binding to each other (due to chemical and/or electrical forces), resulting in crystal aggregation (Figure 26.2). Urinary pH influences the solubility of various lithogenic ions. Uric acid and cystine are more soluble in alkaline urine (pH >7.0).

Crystal retention and formation of calculi take place initially in the papillary duct. Disorders of metabolism, or endocrine or urological abnormalities may lead to the development of crystallized material in the urinary tract (Figure 26.3).

Any condition that results in urinary stasis (i.e., ureteropelvic junction obstruction or vesicoureteral reflux [VUR]) promotes the growth of a stone by increasing the excretion of stone-forming constituents, crystal aggregation, and retention, and a decrease in the excretion of inhibitors or complexing agents. It is very important to bear in mind that in reality, a combination of factors are involved in the genesis of urinary calculi.

CLINICAL PRESENTATION

The clinical manifestations of pediatric urinary stones are dependent on a number of factors:

- Size of the stone
- Location of the stone
- Degree of obstruction to the flow of urine
- Presence of infection
- Presence or absence of a normal contralateral renal unit

Presentation tends to be age dependent, with symptoms such as flank pain and hematuria being more common in older children. Nonspecific symptoms (e.g., irritability and vomiting) are more common in younger children.

Most symptoms related to urolithiasis occur when the calculus becomes lodged in the ureter, causing partial or complete obstruction. Typically, an obstructing calculus causes either renal colic and/or an infection. Renal colic, which occurs in approximately 40%–75% of children with urolithiasis,[9,18] presents with a sudden onset of severe cramp-like flank, abdominal, or pelvic pain associated with gastrointestinal symptoms (nausea and vomiting). Irritative voiding symptoms (i.e., dysuria, urgency, and frequency) occur when the calculus is in the distal one-third of the ureter. In some patients, the pain can present as diffuse abdominal pain and can obscure the clinical picture, delaying the correct diagnosis.[19]

Microscopic or macroscopic hematuria has been reported in up to 90% of children with urinary stones.[20]

Urinary tract infection (UTI) may complicate the clinical presentation, especially in an obstructed kidney, and may not be associated with acute renal colic, but rather persistent flank pain. The combination of flank pain and fever should immediately raise the suspicion for the presence of acute pyelonephritis occurring in the setting of an obstructed calculus, and this requires emergent intervention.

Children with urethral stones often present with terminal hematuria or the inability to void.

On physical examination, most children will be restless and costovertebral angle (CVA) tenderness may be elicited on the affected side. This presentation is less specific in younger children or renal transplant patients. Children under 5 years of age frequently present with symptoms suggestive of a UTI. Asymptomatic stones may be identified in children who are undergoing abdominal imaging for nonurological diagnoses (i.e., acute appendicitis).

EVALUATION OF THE PATIENT WITH UROLITHIASIS

History and Physical Examination

The initial evaluation of a pediatric patient with urolithiasis may suggest the diagnosis through a complete history and physical exam. The evaluation should begin with a review of the history and include questions regarding the following:

- Prematurity (especially with the use of furosemide), supplemental vitamin D, or enteral or parenteral nutrition formulas high in calcium and/or phosphorus
- Current medications (i.e., steroids, chemotherapeutic agents, diuretics, and protease inhibitors)
- Concurrent illnesses (i.e., cystic fibrosis, neoplasms, and seizures)
- Recurrent skeletal fractures, which could indicate the presence of hyperparathyroidism or other bone disease
- Nutritional habits (i.e., ketogenic diet, dietary excesses or deficiencies, and type and amount of fluid intake)
- Family history of nephrolithiasis, gout, or bowel disease

A wide variety of medical conditions can be associated with urolithiasis in children. These include gastrointestinal disorders resulting in malabsorption, chronic corticosteroid treatment, cystic fibrosis, myelodysplasia, and immobilization. The family history is helpful in patients with autosomal recessive disorders, such as cystinuria and primary hyperoxaluria, or with autosomal dominant diseases, such as renal tubular acidosis (RTA) or the syndrome of idiopathic calcium oxalate urolithiasis.

The physical examination should screen for chronic disease, including failure to thrive (distal RTA); hypertension as an indicator of underlying renal parenchymal injury; the characteristic bony deformities of rickets; photophobia due to band keratopathy (hypercalcemia-induced metastatic calcification); and evidence of UTI.

Imaging

The radiographic workup of a child with suspected urolithiasis is relatively straightforward. Recently, renal and bladder ultrasound emerged as the initial imaging modality of choice for children with suspected stone disease.[21,22] The current use of intravenous pyelography (IVP) is very limited in the pediatric population due to concerns about the risks of cumulative radiation exposure. Imaging

TABLE 26.2 Radiodensity of calculi on plain film imaging

Radiopaque calculi	Radiolucent calculi
Calcium oxalate	Uric acid
Calcium phosphate	2,8-Dihydroxyadenine
Struvite (carbonate Triamterene apatite)	Xanthine
Cystine	Silica

modalities, such as plain films of the abdomen (kidney, ureter, and bladder [KUB]), can be useful in detecting stones as well, and also suggesting the type of calculi (Table 26.2). *Calcium oxalate stones are usually less than 2 cm in size, whereas struvite, uric acid, or cystine stones may fill the entire collecting system, i.e., stag horn calculi.*

Currently, in both adult and pediatric stone patients, the unenhanced, helical computerized tomography (CT) scan is the "gold standard" technique for radiological evaluation of acute flank or abdominal pain.[23,24] It allows for an accurate and timely diagnosis of obstructed urinary calculi and can also detect extraurinary lesions.[25] CT scanners are readily available in most pediatric institutions and have the advantages of the brevity of the scan and avoidance of intravenous contrast (and any associated adverse reactions). At the same time, there are legitimate concerns about radiation exposure and lifetime risk of radiation-induced cancer.[26] Therefore, we recommend that the initial study for a child with a suspected stone be a renal bladder ultrasound.

Voiding cystourethrogram and renal nuclear scintigraphy may be necessary to rule out associated anatomical abnormalities in some patients. Children with suspected neurogenic bladder and significant voiding dysfunction might benefit from urodynamic studies, to complete their evaluation when dealing with chronic or recurrent urolithiasis.

Laboratory Evaluation

The evaluation of the patient may be divided into two phases—evaluation during an acute stone episode to direct therapy and subsequent evaluation to determine the underlying etiology of the stone. Owing to the high incidence of predisposing factors for urolithiasis in children (up to 75%), as well as the frequency of stone recurrences (up to 65%),[18] a complete evaluation of every child after the very first urinary stone is advisable.[27,28]

During the acute phase, the following tests are recommended:

- Urine for urinalysis and Culture and Sensitivity (C&S). (Urinalysis usually demonstrates hematuria, while pyuria may be a first sign of UTI, which is confirmed with a urine culture.)
- Serum electrolytes, blood urea nitrogen (BUN), and creatinine. (Determination of serum creatinine is helpful in grossly evaluating the renal function.)
- Complete blood cell count (CBC).
- Serum for Ca^{++}, phosphorous, magnesium, and Parathyroid hormone (PTH) levels may be useful in determining the type of stone being treated.

After treating the acute stone episode, it is of critical importance to collect a 24-hour urine sample in order to determine a stone risk profile and to rule out any subtle metabolic abnormalities.[9,29] The urine collection is evaluated for volume, pH, calcium, uric acid, creatinine, sodium, oxalate, citrate, and cysteine.

Supersaturation indices are felt to accurately predict stone composition, and they may be a more precise predictor of response to therapy.[30,31] We prefer two consecutive 24-hour urine samples as initial evaluation, ideally after the patient is free of stones. During the collection of 24-hour urine samples, the patient should maintain his or her usual diet and fluid intake. We use urinary supersaturation values as the principal laboratory benchmark index of possible crystal formation. Adult reference ranges for urinary supersaturation indices do not accurately reflect the pathophysiology in children.[32] We have shown that there are significant differences in the normal ranges of urine chemistries of children and adults (Table 26.3).[33] Calcium, oxalate, and citrate levels are significantly higher in children than adults when referenced by creatinine. Chemical analysis and determination of the composition of the stone (with polarization microscopy, infrared imaging, or x-ray diffraction) should be performed whenever possible. The patient should be given a urine strainer to retrieve any stones that are passed in his or her urine.

In the next section, we discuss the pathophysiology and specific treatment of the various types of stones encountered in children.

TABLE 26.3 Mean pediatric and adult urine chemistry values

Parameter	Pediatric	Adult	*P*-value
Urine pH	6.44 ± 0.40	6.05 ± 0.41	<0.001
SS Uric acid	0.59 ± 0.53	1.14 ± 0.99	<0.001
SS Ca oxalate	7.88 ± 4.13	7.85 ± 6.30	1.00
SS Ca phosphate	2.48 ± 1.31	1.42 ± 1.19	<0.001
Citrate/Cr (mg/g)	592 ± 460	373 ± 216	0.01
Oxalate/Cr (mg/g)	41.2 ± 26.7	23.1 ± 15.0	<0.001
Ca/Cr (mg/g)	172 ± 99	113 ± 55	0.001
Uric acid/Cr (mg/g)	623 ± 390	396 ± 89	0.01

Abbreviations: SS, supersaturation; Ca, calcium; Cr, creatinine.

Up to 90% of all pediatric kidney stones in the United States are composed of calcium oxalate; these stones are usually mixed calculi with some component of hydroxyapatite, or uric acid.[34,35] Around 5% of stones composed of struvite (magnesium ammonium phosphate) are usually encountered in the clinical setting of recurrent UTI. Less than 5% of stones are uric acid, brushite (calcium monohydrogen phosphate), or cystine.[35]

IDIOPATHIC CALCIUM OXALATE UROLITHIASIS

Hypercalciuria

Hypercalciuria is one of the most common predisposing metabolic factors for stone formation in children. Normal calcium excretion in children is less than 4 mg/kg/day. In general, children with a history of calcium oxalate urolithiasis excrete a higher fraction of dietary calcium in their urine than unaffected children.[18] Hypercalciuria is found in up to 50% of stone-forming children.[18,36] Microscopic or gross hematuria may be encountered in children with hypercalciuria without urolithiasis, although up to 20% of them will develop stones within 5 years.[37,38] Hypercalciuria has also been reported in association with the urinary frequency–dysuria syndrome.[39] Hypercalciuria is seen with a higher prevalence in children with Beckwith–Wiedemann syndrome and cystic fibrosis than in the normal population.[40] Initial studies of idiopathic hypercalciuria (normocalcemic hypercalciuria without an obvious etiology) suggested two relatively easily defined and genetically distinct subtypes of hypercalciuria, "renal" and "absorptive."[41] Some reports have postulated that absorptive and renal forms of hypercalciuria appear to represent a continuum of a single disease process.[42]

Absorptive hypercalciuria is by far the most common cause of excessive urinary calcium. It is due to one of the following causes of an increased intestinal absorption of calcium: overly aggressive vitamin D supplementation or excessive ingestion of calcium-containing foods (milk–alkali syndrome). Increased intestinal calcium absorption produces a corresponding increase in serum calcium levels. Typically, serum PTH is in the low–normal range in absorptive hypercalciuria because of feedback from the high-serum calcium level. Fasting urinary calcium levels are usually within the normal range in these patients.

Three types of absorptive hypercalciuria have been defined. *Type I* patients have hypercalciuria without calcium load. It is relatively uncommon and is the most severe type of absorptive hypercalciuria. *Type II* is the most common variety, where patients have hypercalciuria only with a high calcium intake. *Type III* is a relatively rare cause of hypercalciuria. In this condition, the underlying etiology is a renal defect that causes excessive urinary phosphate excretion. It is suspected to be due to an inactivation of the renal epithelial sodium-phosphate cotransporter—NaPi2. The continuous urinary phosphate loss rapidly depletes the serum phosphate level, causing hypophosphatemia. This results in an activation of vitamin D-3, which increases intestinal absorption of both phosphate and calcium. The absorbed calcium is ultimately excreted in the urine, causing the hypercalciuria.

Renal hypercalciuria is due to a specific defect in the kidneys that allows excessive obligatory urinary calcium excretion regardless of serum calcium levels, body stores, or calcium ingestion. The calcium-to-creatinine ratio is usually high (>0.20). The loss of serum calcium into the urine produces a mild hypocalcemia and secondary hyperparathyroidism, which is useful in diagnosing this condition. Renal leak hypercalciuria is far less common than absorptive hypercalciuria.

Hyperoxaluria

This condition is discussed in depth later in the chapter in the "Primary Hyperoxaluria" section. Up to 20% of patients with idiopathic calcium oxalate urolithiasis will have hyperoxaluria.[18] Oxalate has a very strong chemical affinity for calcium; calcium oxalate has a relatively low solubility. This is most frequently due to *idiopathic hyperoxaluria*, in which case urine oxalate values are only mildly elevated. It may be due to simple dietary excess of high-oxalate food sources or increased endogenous oxalate production. *In patients with enteric hyperoxaluria, calcium stones develop because of fat malabsorption, which in turn results in colonic hyperabsorption of ingested oxalate. The latter occurs because malabsorbed fatty acids bind luminal calcium, which is then unavailable to precipitate and prevent the uptake of ingested oxalate.*[43] Enteric hyperoxaluria is seen in patients with intestinal malabsorption or inflammatory bowel disease and may be treated with dietary adjustment and citrate supplementation.

Hyperuricosuria

Hyperuricosuria commonly occurs in patients with idiopathic calcium oxalate urolithiasis.[44,45] Hyperuricosuria may be the result of a diet high in purines or uricosuric drugs, or from tubular defects, such as an isolated defect in renal tubular urate reabsorption, or from generalized tubular dysfunction. It can also occur in patients undergoing chemotherapy with rapid cell turnover, and in those who are in a negative nitrogen balance (catabolic state). Hyperuricosuria leads to calcium oxalate crystallization by heterogeneous nucleation and by reducing the levels of urinary inhibitors.[46]

Hypocitraturia

Hypocitraturia is a common risk factor for urinary stone formation in patients with idiopathic calcium oxalate urolithiasis.[36,47] *Urinary citrate has a direct inhibitory effect on the crystallization and precipitation of calcium salts.* It binds to calcium ions in the urine, reducing calcium ion activity, which results in a lowering of the supersaturation of calcium phosphate and calcium oxalate. It also increases the inhibitory activity of other urine macromolecules (e.g., Tamm–Horsfall protein) and may reduce the expression of urinary osteopontin, which is an important component of the protein matrix of urinary stones. In addition, urinary citrate excretion can increase urinary pH, which negatively influences uric acid crystallization and uric acid stone formation. Citrate excretion is impaired by acidosis,

TABLE 26.4 Dietary recommendations for pediatric patients with calcium urolithiasis

Nutrient	Dietary recommendation
Fluid intake	Maintain urine output >2 L/day for adolescents and >20 ml/kg/day for younger children
Dietary sodium	No added salt diet (maintain Na <2 g/day)
Dietary calcium	Recommended daily allowance of calcium for age; avoid calcium restriction in children
Dietary protein	Recommended daily allowance; avoid excessive animal protein intake
Dietary potassium	Five servings per day of high-potassium, low-oxalate foods
Dietary phosphorus	Recommended daily allowance
Dietary magnesium	Recommended daily allowance

hypokalemia (causing intracellular acidosis), high-animal-protein diet (with an elevated acid-ash content), and UTI. Acidosis reduces urinary citrate by both enhancing renal tubular reabsorption and reducing the synthesis of citrate. *RTA is the most common cause of hypocitriuria in children.*

Medical Management

Since the single greatest risk factor of pediatric urinary stones is a low urinary flow rate,[48] *the management of all patients with metabolic stones starts with maintaining an adequate level of oral fluid intake even in young children.* One should strive to maintain a urine output greater than 2 L/day for adolescents and approximately 35 mL/kg/day for children.[49,50] Carbonated beverages are to be avoided and do not count as an appropriate oral fluid in these patients.

Calcium restriction in the growing infant, child, or adolescent should be avoided, as it only increases the risk for poorly mineralized bones. There appears to be widespread agreement that restriction of calcium intake contributes to the severity of a patient's osteopenia.[51,52] Individuals having elevated urine sodium–potassium ratios seem most responsive to the hypocalciuric effects of increased potassium intake in combination with a low-salt diet.[53] Dietary manipulations should initially be directed toward dietary excesses or deficiencies, and placing the child on a balanced and nutritious diet (see Table 26.4). The most frequently used medications to correct hypercalciuria are thiazide diuretics (1 mg/kg/day), which act to lower urinary calcium excretion by increasing the fractional calcium absorption by the distal nephron.[54] If RTA is suspected, potassium or sodium citrate is indicated, as it corrects the systemic acidosis, hypercalciuria, hypocitraturia, and hypocalemia.[55] Children with Type III absorptive hypercalciuria (phosphate leak) may benefit from treatment with orthophosphates.[56] Patients with urolithiasis secondary to a ketogenic diet need to be managed in close consultation with their neurologist, as these patients are on a very strictly regimented diet, in terms of volume and caloric intake.[57]

HYPERCALCEMIC STATES

Hyperparathyroidism

Resorptive hypercalciuria is due to the loss of calcium from the body's normal stores in the bony skeleton and is typically diagnosed in children with hyperparathyroidism. Although primary hyperparathyroidism is not a common cause of hypercalcemic hypercalciuria in children, it must be considered in a patient with elevated serum calcium.[58] In this condition, calcium is released from bone in response to the increased activity of osteoclasts caused by excessive and inappropriate serum PTH levels. This causes significant hypercalcemia. *Under normal conditions, PTH causes the kidney to limit calcium excretion, but with the overwhelming serum calcium load produced with hyperparathyroidism, the kidneys are forced to excrete the extra calcium into the urine, resulting in hypercalciuria.*

Immobilization

Immobilization of children is the most common cause in North America of secondary hypercalciuria.[7] The patients primarily at risk are those acutely immobilized for the management of fractures, postoperative management, as opposed to those with static neurological disorders who are chronically bedridden (i.e., spastic quadriplegia).

Others

Gastrointestinal hyperabsorption can be secondary to symptomatic vitamin D intoxication characterized by failure to thrive, anorexia, polyuria and dehydration, and variable degrees of renal insufficiency. The hypercalcemia of sarcoidosis is due to excessive $1,25(OH)_2$ D3 production by alveolar macrophages and in sarcoid granulomas. In the management of these conditions associated with hypercalcemia, it is critical to identify the underlying cause and correct it.

URIC ACID LITHIASIS

Uric acid calculi are radiolucent and comprise up to 5% of the urinary calculi encountered in pediatric patients. These stones are usually white or orange. *Uric acid crystals are orange and can often be mistaken for blood by the patient or their parents.* A pH below 5.8 promotes uric acid crystal precipitation since they are poorly soluble in acidic urine. In the familial, or *idiopathic*, form of the disease, affected children have *hyperuricosuria* and normal uric acid serum concentration. Generalized dysfunction of tubular reabsorption, as seen in patients with Wilson's disease, or various forms of the Fanconi syndrome are associated with familial hyperuricosuria.

Disorders associated with *overproduction of uric acid* include inborn errors of metabolism, such as Lesch–Nyhan syndrome and Type I glycogen storage disease (glucose-6-phosphatase deficiency).[59] Uric acid overproduction can also occur secondary to myeloproliferative disorders (presenting acutely or in relapse), or other causes of cell breakdown (catabolic states induced by neoplasms or chemotherapy). Hyperuricosuria may be the result of a high purine intake or uricosuric drugs (such as probenecid or salicylate) or from tubular defects, such as an isolated defect in renal tubular urate reabsorption, or from generalized tubular dysfunction.[60] Chronic diarrhea1 syndromes (e.g., ulcerative colitis and regional enteritis) or jejunoileal bypass surgery may cause uric acid lithiasis by inducing a net alkali deficit and lowering urine volume (thereby reducing urinary pH and augmenting urinary concentration of uric acid, respectively).[61] The majority of patients with hyperuricosuria have coexistent hypercalciuria; therefore, calcium oxalate urolithiasis may be seen in these children as well.[44]

Since most of these patients have a low volume of chronically acidic urine throughout the day, increasing oral fluid intake and urinary alkalization to a pH of 6.5–7.0 with potassium citrate or sodium bicarbonate are the primary goals of treatment. However, alkalinization of the urine above pH 7.0 can promote calcium phosphate stone formation. Patients with hyperuricemia secondary to myeloproliferative disorders may benefit from decreasing uric acid production with the xanthine oxidase inhibitor allopurinol. A rare complication of prolonged allopurinol therapy is the formation of xanthine stones.[62]

RENAL TUBULAR SYNDROMES

Renal tubular acidosis

RTA is a term applied to several clinical syndromes of metabolic acidosis that result from specific defects in renal tubular hydrogen ion secretion and urinary acidification. Three major types are currently recognized and are differentiated based on the nature of the tubular defect. Stones are composed principally of calcium phosphate (brushite), although calcium oxalate and struvite stones may be seen alone or in combinations.

In *Type 1 (distal) RTA*, the primary functional abnormality is the inability of the distal nephron to establish and maintain a hydrogen ion gradient between the tubular fluid and the blood. As a result, the urine remains inappropriately alkaline regardless of the severity of the systemic acidemia. Type 1 RTA is associated with renal stone disease in up to 70% of cases. Factors contributing to stone formation include increased urinary pH, hypercalciuria, and hypocitraturia.[63,64] Obstructive uropathy is an example of an etiology of distal RTA.

In *Type 2 (proximal) RTA*, the primary defect is a failure of bicarbonate reabsorption in the proximal tubule leading to bicarbonate wasting. However, the kidney is able to acidify the urine appropriately and to excrete the daily load of acid, as distal tubular function is spared. Nephrolithiasis and nephrocalcinosis are not seen in proximal RTA.[63]

In *Type 4 RTA*, chronic renal parenchymal damage leading to moderate reductions in glomerular filtration rate produces hyperkalemic, hyperchloremic metabolic acidosis in conjunction with bicarbonaturia, decreased ammonium excretion, and subnormal net acid excretion.[63] Nephrolithiasis and nephrocalcinosis are absent in Type 4 RTA.

Type 1 RTA may present as an isolated entity, or it may be the secondary manifestation of a variety of systemic and renal disorders, including Sjögren's syndrome, Wilson's disease, and primary biliary cirrhosis, and in patients who have undergone a jejunoileal bypass. Children usually present early with familial (autosomal dominant) Type 1 RTA. Infants generally present with vomiting and/or diarrhea (>33%) and failure to thrive (>50%), with subsequent growth retardation. Less than 10% have nephrolithiasis and nephrocalcinosis. Children present with metabolic bone disease (osteomalacia) or with signs and symptoms related to stone disease.

Patients with Type 1 RTA will present with a hypokalemic, hyperchloremic metabolic acidosis. In these patients, their urinary pH will never fall below 5.5 no matter how low the serum bicarbonate level.[63] Hypocitraturia and hypercalciuria will only be found in Type 1 RTA, but they are not specific for this disorder. A diagnostic workup for the presence of incomplete distal RTA is indicated when nephrocalcinosis or recurrent nephrolithiasis of unclear etiology occurs in the absence of spontaneous, nonanion gap acidosis. While these patients do not have spontaneous metabolic acidosis, they are unable to acidify the urine appropriately when presented with an acid load.[65] This condition is diagnosed by means of an ammonium chloride loading test and monitoring the urine pH. If at any time the urinary pH falls below 5.5, the diagnosis of RTA can be excluded.

Cystinuria

Cystinuria is a complex autosomal recessive disorder, characterized by an abnormality in a specific transport system located in the brush-border membrane of the proximal straight renal tubule and the small intestine. The transporter (SLC3A1 dibasic amino acid transporter) is encoded on chromosome 2p21. Cystinuria results from an excessive urinary excretion of cystine (the disulfide dimer of cysteine) and the dibasic amino acids arginine, lysine, and ornithine.[66,67] Cystine has poor solubility in the normal urinary pH range, and a pH below 7 causes cystine to precipitate. Cystine stones are usually very hard and resistant to fragmentation by extracorporeal shock wave lithotripsy (ESWL).

There are three subtypes of cystinuria, and it occurs with a frequency of 1 in 15,000 live births[68,69] and accounts for 1%–5% of children with metabolic urolithiasis in industrialized countries.[7,35] Cystine crystals are characteristically flat, hexagonal, and colorless. Cystine crystals are diagnostic, but are detected in only 19%–26% of homozygous cystinuric patients.[66] Cystinuria has been associated with hyperuricemia, uric acid urolithiasis, hemophilia, retinitis pigmentosa, muscular dystrophy, muscular hypotonia, mental retardation, trisomy 21, and hereditary pancreatitis.

The treatment goals of this condition include maintaining a high fluid intake to reduce cystine saturation (the goal is less than 300 mg cystine/L of urine), with urinary flow rates of up to 50 mL/kg/24 hours.[70,71] Further reduction of cystine concentration can be achieved with a diet low in protein and sodium. Urinary alkalization with potassium citrate at a pH of approximately 7.6 should be maintained in all patients. In children in whom hydration and alkalization have failed, D-penicillamine (20–50 mg/kg/day) and/or alpha-mercaptopropionyglycine (Thiola) (15 mg/kg/day) can be effective in decreasing the rate of stone formation. These drugs can be associated with serious side effects, and patients taking them must be monitored very closely for bone marrow suppression, nephrotic syndrome, and complications resembling systemic lupus and Goodpasture syndrome. Thiola has been reported to be better tolerated by pediatric patients. Vitamin B-6 supplementation must be added for patients being treated with either medication. Captopril has also been shown to be effective in lowering the urinary cystine level in homozygous cystinuric patients, by forming a thiol-cysteine mixed disulfide compound that is more soluble in urine than cystine.[72] Patients with cystinuria are at a very high risk for recurrent urolithiasis.[73,74]

ENZYMATIC DISORDERS

Primary Hyperoxaluria

This is a very rare but serious disorder caused by a congenital defect resulting in very high levels (>200 mg/day) of endogenous oxalate production.[75] Without treatment, the prognosis for these patients is poor. Renal failure occurs in 50% of patients by age 15 years and in 80% by age 30 years. Standard dialysis for uremia cannot remove enough serum oxalate to protect the kidneys and other organs from widespread calcium oxalate deposition (i.e., oxalosis) and calcium oxalate stone production.

Type I hyperoxaluria is the more common variety. It occurs in 1 per 120,000 live births and is transmitted as an autosomal recessive trait. It is caused by a deficiency of the peroxisomal liver-specific alanine–glyoxylate aminotransferase enzyme (i.e., *AGT*). Pyridoxine (vitamin B-6) is a cofactor in this chemical pathway, which normally converts glyoxylic acid ($C_2H_2O_3$) to glycine. When the pathway is blocked because of a deficiency or absence of this enzyme, it results in high levels of glycolic and oxalic acid, which are readily converted to oxalate that is then excreted in the urine.

The median age for presentation of initial symptoms related to hyperoxaluria is 5 years. Oxalate deposition can occur in other organs (e.g., bones, joints, eyes, and heart). In particular, bone tends to be the major repository of excess oxalate in patients with primary hyperoxaluria. Bone oxalate levels are negligible in healthy subjects. Oxalate deposition in the skeleton tends to increase bone resorption and decrease osteoblast activity. Because of the clinical variability, the diagnosis is often overlooked and only realized after the loss of a transplanted kidney.[76] Symptoms occur relatively late and are associated with very serious complications; screening all pediatric patients who have stones for hyperoxaluria is important. Discovering this condition may allow earlier testing, detection, diagnosis, and preemptive therapy in affected siblings.

Type II hyperoxaluria is much less common than Type I hyperoxaluria and is due to a deficiency of D-glycerate dehydrogenase (DGDH). This deficiency promotes the conversion of glyoxylate to oxalate. The degree of hyperoxaluria is approximately the same between the two types of primary hyperoxaluria. End-stage renal disease is slightly less common in patients with this form of primary hyperoxaluria than in those with Type I hyperoxaluria.

Primary hyperoxaluria requires vigorous management and careful follow-up. Therapy includes promoting a high urinary flow rate around the clock, and restricting dietary oxalate. Restriction of dietary calcium can result in increased oxalate absorption via the gastrointestinal tract and should be avoided.[20] Pyridoxine supplements (25–250 mg daily) have been shown to lower oxalate production and decrease the need for renal–liver transplantation.[77] Pyridoxine is generally not effective in patients with Type II primary hyperoxaluria.

Curative treatment involves a combined kidney and liver transplantation. Renal transplantation alone is insufficient because the liver defect causing the hyperoxaluria is not corrected. In selected patients, an early liver transplantation prior to the development of overt renal failure may preserve the native kidneys, thus avoiding the need for renal transplantation.

Xanthinuria

Xanthinuria is a descriptive term for excessive urinary excretion of the purine base xanthine. The two inherited forms of xanthinuria result from a deficiency of the enzyme xanthine dehydrogenase, which is responsible for degrading hypoxanthine and xanthine to uric acid. The resultant increase in plasma levels and excess urinary excretion of the highly insoluble xanthine, leads to urolithiasis, arthropathy, myopathy, crystal nephropathy, or renal failure.[78] More than half of the xanthine uroliths occur in children younger than 10 years. Iatrogenic xanthinuria can occur during allopurinol therapy, which is used to reduce urine uric acid excretion in conditions with endogenous overproduction of uric acid. Inhibition of xanthine dehydrogenase by allopurinol may lead to accumulation and urinary excretion of xanthine. No specific therapies are available for classic xanthinuria.

Lesch–Nyhan Syndrome (Hyperuricosuria)

The enzymatic defect associated with Lesch–Nyhan syndrome is a deficiency of the enzyme hypoxanthine-guanine phosphoribosyl transferase (HPRT).[79] HPRT normally plays a key role in the recycling of the purine bases, hypoxanthine and guanine, into the purine nucleotide pools. In the absence of HPRT, these purine bases are degraded and excreted ultimately as uric acid. In addition to the failure of purine recycling, the rate of synthesis of purines is markedly increased, presumably to compensate for purines lost by the failure of the salvage process.

This is a genetic disorder associated with overproduction of uric acid, neurological disability, and behavioral problems. The overproduction of uric acid is associated with hyperuricemia. If left untreated, it can produce nephrolithiasis with renal failure, gouty arthritis, and solid subcutaneous deposits known as tophi. The neurological disability encompasses a spectrum of extrapyramidal signs, including dystonia, choreoathetosis, and occasionally ballismus. The behavioral problems include cognitive dysfunction, aggressive and impulsive behaviors, and self-mutilation.

The majority of patients present between 3 and 12 months of age with delayed motor development, most commonly hypotonia or failure to reach normal motor milestones. A smaller number of patients present with complications related to the overproduction of uric acid. Sometimes the parents give a history of "orange sand" in the diapers, which is caused by uric acid crystalluria and microhematuria. Other patients may present with renal failure or frank hematuria, resulting from nephrolithiasis. The control of uric acid requires allopurinol, which inhibits the metabolism of hypoxanthine and xanthine to uric acid by the enzyme xanthine oxidase. Generous hydration at all times is essential. Hydration should be increased during periods of increased fluid loss, such as a febrile illness or recurrent emesis.

INFECTION STONES

Infection-related stones constitute about 2%–3% of the stones in pediatric patients and most commonly are seen in younger children (less than 6 years of age). *Infection by urea-splitting bacteria results in increased urinary pH (large amount of NH_4) and increased urinary magnesium ammonium phosphate, conditions favoring the formation of struvite stones.*[80] A urinary pH of 6.8 or more results from the action of the bacterial enzyme urease on the urinary urea. The resultant stones (which have a tendency to grow rapidly and form stag horn calculi) are intrinsically contaminated by bacteria, and the affected children all have findings of persistent pyuria, bacteriuria, and struvite crystalluria. More than 45 types of microorganisms are capable of urease production. *Proteus* species are isolated in more than 70% of all patients with infected stones, although *Pseudomonas*, *Klebsiella*, *Streptococcus*, and *Mycoplasma* species may also produce urease.[81]

To treat struvite stones successfully, the stone harboring the infection should be eliminated completely. In such cases, antibiotics alone cannot reach microorganisms and urinary infection recurs as soon as antibiotics are withdrawn. Select patients will benefit from hemiacidrin irrigation, which can dissolve some struvite stones. Acetohydroxamic acid (AHA), a urease inhibitor, is available for the management of stones caused by infection.[82] Genitourinary tract abnormalities predispose to the formation of infected stones (most frequently by obstruction); therefore, careful urological evaluation of the patient with infected stones is mandatory.[34] Findings of obstruction or a structurally anomalous urinary tract in these patients do not obviate the need for careful metabolic assessment. In one study of 66 patients with structural anomalies of the urinary tract, 36% had coexistent metabolic abnormalities. In the same study, of the 41 patients with infection-related stones, 56% had genitourinary anomalies and 29% had metabolic abnormalities.[18]

MISCELLANEOUS STONES

Triamterene Stones

Triamterene is a potassium-sparing diuretic. Seventy percent of the orally administered medication appears in the urine. One in 1500 patients on this medication will develop stones.[83]

Sulfadiazine Stones

Sulfadiazine is a medication that is used to treat toxoplasmosis in patients with HIV. Sulfadiazine crystalluria occurs in up to 49% of the patients treated with this medication. The exact incidence of this medication causing stones is unknown. Most sulfadiazine stones are radiolucent. Treatment includes hyperhydration and alkalinization of the urine.[84]

Indinavir (Crixivan) Stones

Indinavir is a protease inhibitor and is used as an antiviral drug in the treatment of HIV. Twenty percent of the administered medication is excreted unchanged in the urine. Patients who do not maintain a urine output of >1.5 L/day while on this medication will often have crystalluria and occasionally develop indinavir stones.[85] Stone development occurs at a higher urine pH (>6.0). These stones are typically radiolucent, and composed of a soft yellowish-brown gelatinous material. Unenhanced CT imaging may fail to demonstrate these stones, and a high degree of suspicion should be maintained in patients at risk for these stones.[86] Due to their soft nature, ESWL is often not useful in treating these stones, but they do respond to hyperhydration and mechanical removal of the stone (i.e., stone basketing).[87]

SUMMARY

Urolithiasis in the pediatric population has diverse etiologies and presentations. With a careful and systematic evaluation of the patient and individualized management strategies, recurrent stones, renal injury, and patient morbidity can be minimized. Once again, we would like to emphasize that the adult urinary values for the metabolic stone risk profile are not accurate for use in pediatric patients.
